Preface to Volume 2

Fortran 90 is not just the long-awaited updating of the Fortran language to modern computing practices. It is also the vanguard of a much larger revolution in computing, that of multiprocessor computers and widespread parallel programming. Parallel computing has been a feature of the largest supercomputers for quite some time. Now, however, it is rapidly moving towards the desktop.

As we watched the gestation and birth of Fortran 90 by its governing “X3J3 Committee” (a process interestingly described by a leading committee member, Michael Metcalf, in the Foreword that follows), it became clear to us that the right moment for moving Numerical Recipes from Fortran 77 to Fortran 90 was sooner, rather than later.

Fortran 90 compilers are now widely available. Microsoft’s Fortran PowerStation for Windows 95 brings that firm’s undeniable marketing force to PC desktop; we have tested this compiler thoroughly on our code and found it excellent in compatibility and performance. In the UNIX world, we have similarly tested, and had generally fine experiences with, DEC’s Fortran 90 for Alpha AXP and IBM’s xlf for RS/6000 and similar machines. NAG’s Fortran 90 compiler also brings excellent Fortran 90 compatibility to a variety of UNIX platforms. There are no doubt other excellent compilers, both available and on the way. Fortran 90 is completely backwards compatible with Fortran 77, by the way, so you don’t have to throw away your legacy code, or keep an old compiler around.

There have been previous special versions of Fortran for parallel supercomputers, but always specific to a particular hardware. Fortran 90, by contrast, is designed to provide a general, architecture-independent framework for parallel computation. Equally importantly, it is an international standard, agreed upon by a large group of computer hardware and software manufacturers and international standards bodies.

With the Fortran 90 language as a tool, we want this volume to be your complete guide for learning how to “think parallel.” The language itself is very general in this regard, and applicable to many present and future computers, or even to other parallel computing languages as they come along. Our treatment emphasizes general

principles, but we are also not shy about pointing out parallelization “tricks” that have frequent applicability. These are not only discussed in this volume’s principal text chapters (Chapters 21–23), but are also sprinkled throughout the chapters of Fortran 90 code, called out by a special “parallel hint” logo (left, above). Also scattered throughout the code chapters are specific “Fortran 90 tips,” with their own distinct graphic call-out (left). After you read the text chapters, you might want simply to browse among these hints and tips.

A special note to C programmers: Right now, there is no effort at producing a parallel version of C that is comparable to Fortran 90 in maturity, acceptance, and stability. We think, therefore, that C programmers will be well served by using this volume for an educational excursion into Fortran 90, its parallel programming constructions, and the numerical algorithms that capitalize on them. C and C++ programming have not been far from our minds as we have written this volume, and we think that you will find that time spent in absorbing its principal lessons (in Chapters 21–23) will be amply repaid in the future, as C and C++ eventually develop standard parallel extensions.

A final word of truth in packaging: **Don't buy this volume unless you also buy (or already have) Volume 1** (now retitled *Numerical Recipes in Fortran 77*). Volume 2 does not repeat any of the discussion of what individual programs actually do, or of the mathematical methods they utilize, or how to use them. While our Fortran 90 code is thoroughly commented, and includes a header comment for each routine that describes its input and output quantities, these comments are *not* supposed to be a complete description of the programs; the complete descriptions are in Volume 1, which we reference frequently. But here's a money-saving hint to our previous readers: If you already own a Second Edition version whose title is *Numerical Recipes in FORTRAN* (which doesn't indicate either "Volume 1" or "Volume 2" on its title page) then take a marking pen and write in the words "Volume 1." There! (Differences between the previous reprintings and the newest reprinting, the one labeled "Volume 1," are minor.)

Acknowledgments

We continue to be in the debt of many colleagues who give us the benefit of their numerical and computational experience. Many, though not all, of these are listed by name in the preface to the second edition, in Volume 1. To that list we must now certainly add George Marsaglia, whose ideas have greatly influenced our new discussion of random numbers in this volume (Chapter B7).

With this volume, we must acknowledge our additional gratitude and debt to a number of people who generously provided advice, expertise, and time (a great deal of time, in some cases) in the areas of parallel programming and Fortran 90. The original inspiration for this volume came from Mike Metcalf, whose clear lectures on Fortran 90 (in this case, overlooking the beautiful Adriatic at Trieste) convinced us that Fortran 90 could serve as the vehicle for a book with the larger scope of parallel programming generally, and whose continuing advice throughout the project has been indispensable. Gyan Bhanot also played a vital early role in the development of this book; his first translations of our Fortran 77 programs taught us a lot about parallel programming. We are also grateful to Greg Lindhorst, Charles Van Loan, Amos Yahil, Keith Kimball, Malcolm Cohen, Barry Caplin, Loren Meissner, Mitsu Sakamoto, and George Schnurer for helpful correspondence and/or discussion of Fortran 90's subtler aspects.

We once again express in the strongest terms our gratitude to programming consultant Seth Finkelstein, whose contribution to both the coding and the thorough testing of all the routines in this book (against multiple compilers and in sometimes-buggy, and always challenging, early versions) cannot be overstated.

WHP and SAT acknowledge the continued support of the U.S. National Science Foundation for their research on computational methods.

Foreword

by Michael Metcalf

Sipping coffee on a sunbaked terrace can be surprisingly productive. One of the *Numerical Recipes* authors and I were each lecturing at the International Center for Theoretical Physics in Trieste, Italy, he on numerical analysis and I on Fortran 90. The numerical analysis community had made important contributions to the development of the new Fortran standard, and so, unsurprisingly, it became quickly apparent that the algorithms for which *Numerical Recipes* had become renowned could, to great advantage, be recast in a new mold. These algorithms had, hitherto, been expressed in serial form, first in Fortran 77 and then in C, Pascal, and Basic. Now, nested iterations could be replaced by array operations and assignments, and the other features of a rich array language could be exploited. Thus was the idea of a “Numerical Recipes in Fortran 90” first conceived and, after three years’ gestation, it is a delight to assist at the birth.

But what *is* Fortran 90? How did it begin, what shaped it, and how, after nearly foundering, did its driving forces finally steer it to a successful conclusion?

The Birth of a Standard

Back in 1966, the version of Fortran now known as Fortran 66 was the first language ever to be standardized, by the predecessor of the present American National Standards Institute (ANSI). It was an all-American affair. Fortran had first been developed by John Backus of IBM in New York, and it was the dominant scientific programming language in North America. Many Europeans preferred Algol (in which Backus had also had a hand). Eventually, however, the mathematicians who favored Algol for its precisely expressible syntax began to defer to the scientists and engineers who appreciated Fortran’s pragmatic, even natural, style. In 1978, the upgraded Fortran 77 was standardized by the ANSI technical committee, X3J3, and subsequently endorsed by other national bodies and by ISO in Geneva, Switzerland. Its dominance in all fields of scientific and numerical computing grew as new, highly optimizing compilers came onto the market. Although newer languages, particularly Pascal, Basic, PL/1, and later Ada attracted their own adherents, scientific users throughout the 1980s remained true to Fortran. Only towards the end of that decade did C draw increasing support from scientific programmers who had discovered the power of structures and pointers.

During all this time, X3J3 kept functioning, developing the successor version to Fortran 77. It was to be a decade of strife and contention. The early plans, in the late 1970s, were mainly to add to Fortran 77 features that had had to be left out of that standard. Among these were dynamic storage and an array language, enabling it to map directly onto the architecture of supercomputers, then coming onto the market. The intention was to have this new version ready within five years, in 1982. But two new factors became significant at that time. The first was the decision that the next standard should not just codify existing practice, as had largely been the case in 1966 and 1978, but also extend the functionality of the language through

innovative additions (even though, for the array language, there was significant borrowing from John Iverson's APL and from DAP Fortran). The second factor was that X3J3 no longer operated under only American auspices. In the course of the 1980s, the standardization of programming languages came increasingly under the authority of the international body, ISO. Initially this was in an advisory role, but now ISO is the body that, through its technical committee WG5 (in full, ISO/IEC JTC1/SC22/WG5), is responsible for determining the course of the language. WG5 also steers the work of the development body, then as now, the highly skilled and competent X3J3. As we shall see, this shift in authority was crucial at the most difficult moment of Fortran 90's development.

The internationalization of the standards effort was reflected in the welcome given by X3J3 to six or seven European members; they, and about one-third of X3J3's U.S. members, provided the overlapping core of membership of X3J3 and WG5 that was vital in the final years in bringing the work to a successful conclusion. X3J3 membership, which peaked at about 45, is restricted to one voting member per organization, and significant decisions require a majority of two-thirds of those voting. Nationality plays no role, except in determining the U.S. position on an international issue. Members, who are drawn mainly from the vendors, large research laboratories, and academia, must be present or represented at two-thirds of all meetings in order to retain voting rights.

In 1980, X3J3 reported on its plans to the forerunner of WG5 in Amsterdam, Holland. Fortran 8x, as it was dubbed, was to have a basic array language, new looping constructs, a bit data type, data structures, a free source form, a mechanism to "group" procedures, and another to manage the global name space. Old features, including COMMON, EQUIVALENCE, and the arithmetic-IF, were to be consigned to a so-called obsolete module, destined to disappear in a subsequent revision. This was part of the "core plus modules" architecture, for adding new features and retiring old ones, an aid to backwards compatibility. Even though Fortran 77 compilers were barely available, the work seemed well advanced and the mood was optimistic. Publication was intended to take place in 1985. It was not to be.

One problem was the sheer number of new features that were proposed as additions to the language, most of them worthwhile in themselves but with the totality being too large. This became a recurrent theme throughout the development of the standard. One example was the suggestion of Lawrie Schonfelder (Liverpool University), at a WG5 meeting in Vienna, Austria, in 1982, that certain features already proposed as additions could be combined to provide a full-blown derived data type facility, thus providing Fortran with abstract data types. This idea was taken up by X3J3 and has since come to be recognized, along with the array language, as one of the two main advances brought about by what became Fortran 90. However, the ramifications go very deep: all the technical details of how to handle arrays of objects of derived types that in turn have array components that have the pointer attribute, and so forth, have to be precisely defined and rigorously specified.

Conflict

The meetings of X3J3 were often full of drama. Most compiler vendors were represented as a matter of course but, for many, their main objective appeared to be to maintain the status quo and to ensure that Fortran 90 never saw the light of

day. One vendor's extended (and much-copied) version of Fortran 77 had virtually become an industry standard, and it saw as its mission the maintenance of this lead. A new standard would cost it its perceived precious advantage. Other large vendors had similar points of view, although those marketing supercomputers were clearly keen on the array language. Most users, on the other hand, were hardly prepared to invest large amounts of their employers' and their own resources in simply settling for a trivial set of improvements to the existing standard. However, as long as X3J3 worked under a simple-majority voting rule, at least some apparent progress could be made, although the underlying differences often surfaced. These were even sometimes between users — those who wanted Fortran to become a truly modern language and those wanting to maintain indefinite backwards compatibility for their billions of lines of existing code.

At a watershed meeting, in Scranton, Pennsylvania, in 1986, held in an atmosphere that sometimes verged on despair, a fragile compromise was reached as a basis for further work. One breakthrough was to weaken the procedures for removing outdated features from the language, particularly by removing no features whatsoever from the next standard and by striking storage association (i.e., `COMMON` and `EQUIVALENCE`) from the list of features to be designated as obsolescent (as they are now known). A series of votes definitively removed from the language all plans to add: arrays of arrays, exception handling, nesting of internal procedures, the `FORALL` statement (now in Fortran 95), and a means to access skew array sections. There were other features on this list that, although removed, were reinstated at later meetings: user-defined operators, operator overloading, array and structure constructors, and vector-valued subscripts. After many more travails, the committee voted, a year later, by 26 votes to 9, to forward the document for what was to become the first of three periods of public comment.

While the document was going through the formal standards bureaucracy and being placed before the public, X3J3 polished it further. X3J3 also prepared procedures for processing the comments it anticipated receiving from the public, and to each of which, under the rules, it would have to reply individually. It was just as well. Roughly 400 replies flooded in, many of them very detailed and, disappointingly for those of us wanting a new standard quickly, unquestionably negative towards our work. For many it was too radical, but many others pleaded for yet more modern features, such as pointers.

Now the committee was deadlocked. Given that a document had already been published, any further change required not a simple but a two-thirds majority. The conservatives and the radicals could each block a move to modify the draft standard, or to accept a revised one for public review — and just that happened, in Champagne-Urbana, Illinois, in 1988. Any change, be it on the one hand to modify the list of obsolescent features, to add the pointers or bit data type wanted by the public, to add multi-byte characters to support Kanji and other non-European languages or, on the other hand, to emasculate the language by removing modules or operator overloading, and hence abstract data types, to name but some suggestions, none of these could be done individually or collectively in a way that would achieve consensus. I wrote:

“In my opinion, no standard can now emerge without either a huge concession by the users to the vendors (`MODULE / USE`) and/or a major change in the composition of the committee. I do not see how members who have worked for up to a decade or more, devoting time and intellectual energy far beyond the call of duty, can be

expected to make yet more personal sacrifices if no end to the work is in sight, or if that end is nothing but a travesty of what had been designed and intended as a modern scientific programming language. . . . I think the August meeting will be a watershed — if no progress is achieved there will be dramatic resignations, and ISO could even remove the work from ANSI, which is failing conspicuously in its task."

(However, the same notes began with a quotation from *The Taming of the Shrew*: "And do as adversaries do in law, / Strive mightily, but eat and drink / as friend." That we always did, copiously.)

Resolution

The "August meeting" was, unexpectedly, imbued with a spirit of compromise that had been so sadly lacking at the previous one. Nevertheless, after a week of discussing four separate plans to rescue the standard, no agreement was reached. Now the question seriously arose: Was X3J3 incapable of producing a new Fortran standard for the international community, doomed to eternal deadlock, a victim of ANSI procedures?

Breakthrough was achieved at a traumatic meeting of WG5 in Paris, France, a month later. The committee spent several extraordinary days drawing up a detailed list of what *it* wanted to be in Fortran 8x. Finally, it set X3J3 an ultimatum that was unprecedented in the standards world: The ANSI committee was to produce a new draft document, corresponding to WG5's wishes, within five months! Failing that, WG5 would assume responsibility and produce the new standard itself.

This decision was backed by the senior U.S. committee, X3, which effectively directed X3J3 to carry out WG5's wishes. And it did! The following November, it implemented most of the technical changes, adding pointers, bit manipulation intrinsic procedures, and vector-valued subscripts, and removing user-defined elemental functions (now in Fortran 95). The actual list of changes was much longer. X3J3 and WG5, now collaborating closely, often in gruelling six-day meetings, spent the next 18 months and two more periods of (positive) public comment putting the finishing touches to what was now called Fortran 90, and it was finally adopted, after some cliff-hanging votes, for forwarding as a U.S. and international standard on April 11, 1991, in Minneapolis, Minnesota.

Among the remaining issues that were decided along the way were whether pointers should be a data type or be defined in terms of an attribute of a variable, implying strong typing (the latter was chosen), whether the new standard should coexist alongside the old one rather than definitively replace it (it coexisted for a while in the U.S., but was a replacement elsewhere, under ISO rules), and whether, in the new free source form, blanks should be significant (fortunately, they are).

Fortran 90

The main new features of Fortran 90 are, first and foremost, the array language and abstract data types. The first is built on whole array operations and assignments, array sections, intrinsic procedures for arrays, and dynamic storage. It was designed with optimization in mind. The second is built on modules and module procedures, derived data types, operator overloading and generic interfaces, together with pointers. Also important are the new facilities for numerical computation including

a set of numeric inquiry functions, the parametrization of the intrinsic types, new control constructs — SELECT CASE and new forms of DO, internal and recursive procedures and optional and keyword arguments, improved I/O facilities, and many new intrinsic procedures. Last but not least are the new free source form, an improved style of attribute-oriented specifications, the IMPLICIT NONE statement, and a mechanism for identifying redundant features for subsequent removal from the language. The requirement on compilers to be able to identify, for example, syntax extensions, and to report why a program has been rejected, are also significant. The resulting language is not only a far more powerful tool than its successor, but a safer and more reliable one too. Storage association, with its attendant dangers, is not abolished, but rendered unnecessary. Indeed, experience shows that compilers detect errors far more frequently than before, resulting in a faster development cycle. The array syntax and recursion also allow quite compact code to be written, a further aid to safe programming.

No programming language can succeed if it consists simply of a definition (witness Algol 68). Also required are robust compilers from a wide variety of vendors, documentation at various levels, and a body of experience. The first Fortran 90 compiler appeared surprisingly quickly, in 1991, especially in view of the widely touted opinion that it would be very difficult to write one. Even more remarkable was that it was written by one person, Malcolm Cohen of NAG, in Oxford, U.K. There was a gap before other compilers appeared, but now they exist as native implementations for almost all leading computers, from the largest to PCs. For the most part, they produce very efficient object code; where, for certain new features, this is not the case, work is in progress to improve them.

The first book, *Fortran 90 Explained*, was published by John Reid and me shortly before the standard itself was published. Others followed in quick succession, including excellent texts aimed at the college market. At the time of writing there are at least 19 books in English and 22 in various other languages: Chinese, Dutch, French, Japanese, Russian, and Swedish. Thus, the documentation condition is fulfilled.

The body of experience, on the other hand, has yet to be built up to a critical size. Teaching of the language at college level has only just begun. However, I am certain that this present volume will contribute decisively to a significant breakthrough, as it provides models not only of the numerical algorithms for which previous editions are already famed, but also of an excellent Fortran 90 style, something that can develop only with time. Redundant features are abjured. It shows that, if we abandon these features and use new ones in their place, the appearance of code can initially seem unfamiliar, but, in fact, the advantages become rapidly apparent. This new edition of *Numerical Recipes* stands as a landmark in this regard.

Fortran Evolution

The formal procedures under which languages are standardized require them either to evolve or to die. A standard that has not been revised for some years must either be revised and approved anew, or be withdrawn. This matches the technical pressure on the language developers to accommodate the increasing complexity both of the problems to be tackled in scientific computation and of the underlying hardware on which programs run. Increasing problem complexity requires more powerful

features and syntax; new hardware needs language features that map onto it well.

Thus it was that X3J3 and WG5, having finished Fortran 90, began a new round of improvement. They decided very quickly on new procedures that would avoid the disputes that bedevilled the previous work: WG5 would decide on a plan for future standards, and X3J3 would act as the so-called development body that would actually produce them. This would be done to a strict timetable, such that any feature that could not be completed on time would have to wait for the next round. It was further decided that the next major revision should appear a decade after Fortran 90 but, given the somewhat discomfiting number of requests for interpretation that had arrived, about 200, that a minor revision should be prepared for mid-term, in 1995. This should contain only “corrections, clarifications and interpretations” and a very limited number (some thought none) of minor improvements.

At the same time, scientific programmers were becoming increasingly concerned at the variety of methods that were necessary to gain efficient performance from the ever-more widely used parallel architectures. Each vendor provided a different set of parallel extensions for Fortran, and some academic researchers had developed yet others. On the initiative of Ken Kennedy of Rice University, a High-Performance Fortran Forum was established. A coalition of vendors and users, its aim was to produce an ad hoc set of extensions to Fortran that would become an informal but widely accepted standard for portable code. It set itself the daunting task of achieving that in just one year, and succeeded. Melding existing dialects like Fortran D, CM Fortran, and Vienna Fortran, and adopting the new Fortran 90 as a base, because of its array syntax, High-Performance Fortran (HPF) was published in 1993 and has since become widely implemented. However, although HPF was designed for data parallel codes and mainly implemented in the form of directives that appear to non-HPF processors as comment lines, an adequate functionality could not be achieved without extending the Fortran syntax. This was done in the form of the PURE attribute for functions — an assertion that they contain no side effects — and the FORALL construct — a form of array assignment expressed with the help of indices.

The dangers of having diverging or competing forms of Fortran 90 were immediately apparent, and the standards committees wisely decided to incorporate these two syntactic changes also into Fortran 95. But they didn’t stop there. Two further extensions, useful not only for their expressive power but also to access parallel hardware, were added: elemental functions, ones written in terms of scalars but that accept array arguments of any permitted shape or size, and an extension to allow nesting of WHERE constructs, Fortran’s form of masked assignment. To readers of *Numerical Recipes*, perhaps the most relevant of the minor improvements that Fortran 95 brings are the ability to distinguish between a negative and a positive real zero, automatic deallocation of allocatable arrays, and a means to initialize the values of components of objects of derived data types and to initialize pointers to null.

The medium-term objective of a relatively minor upgrade has been achieved on schedule. But what does the future hold? Developments in the underlying principles of procedural programming languages have not ceased. Early Fortran introduced the concepts of expression abstraction ($X=Y+Z$) and later control expression (e.g., the DO loop). Fortran 77 continued this with the if-then-else, and Fortran 90 with the DO and SELECT CASE constructs. Fortran 90 has a still higher level of expression abstraction (array assignments and expressions) as well as data structures and even full-blown abstract data types. However, during the 1980s the concept of objects

came to the fore, with methods bound to the objects on which they operate. Here, one particular language, C++, has come to dominate the field. Fortran 90 lacks a means to point to functions, but otherwise has most of the necessary features in place, and the standards committees are now faced with the dilemma of deciding whether to make the planned Fortran 2000 a fully object-oriented language. This could possibly jeopardize its powerful, and efficient, numerical capabilities by too great an increase in language complexity, so should they simply batten down the hatches and not defer to what might be only a passing storm? At the time of writing, this is an open issue. One issue that is not open is Fortran's lack of in-built exception handling. It is virtually certain that such a facility, much requested by the numerical community, and guided by John Reid, will be part of the next major revision. The list of other requirements is long but speculative, but some at the top of the list are conditional compilation, command line argument handling, I/O for objects of derived type, and asynchronous I/O (which is also planned for the next release of HPF). In the meantime, some particularly pressing needs have been identified, for the handling of floating-point exceptions, interoperability with C, and allowing allocatable arrays as structure components, dummy arguments, and function results. These have led WG5 to begin processing these three items using a special form of fast track, so that they might become optional but standard extensions well before Fortran 2000 itself is published in the year 2001.

Conclusion

Writing a book is always something of a gamble. Unlike a novel that stands or falls on its own, a book devoted to a programming language is dependent on the success of others, and so the risk is greater still. However, this new *Numerical Recipes in Fortran 90* volume is no ordinary book, since it comes as the continuation of a highly successful series, and so great is its significance that it can, in fact, influence the outcome in its own favor. I am entirely confident that its publication will be seen as an important event in the story of Fortran 90, and congratulate its authors on having performed a great service to the field of numerical computing.

Geneva, Switzerland
January 1996

Michael Metcalf

License Information

Read this section if you want to use the programs in this book on a computer. You'll need to read the following Disclaimer of Warranty, get the programs onto your computer, and acquire a Numerical Recipes software license. (Without this license, which can be the free "immediate license" under terms described below, the book is intended as a text and reference book, for reading purposes only.)

Disclaimer of Warranty

We make no warranties, express or implied, that the programs contained in this volume are free of error, or are consistent with any particular standard of merchantability, or that they will meet your requirements for any particular application. They should not be relied on for solving a problem whose incorrect solution could result in injury to a person or loss of property. If you do use the programs in such a manner, it is at your own risk. The authors and publisher disclaim all liability for direct or consequential damages resulting from your use of the programs.

How to Get the Code onto Your Computer

Pick one of the following methods:

- You can type the programs from this book directly into your computer. In this case, the *only* kind of license available to you is the free "immediate license" (see below). You are not authorized to transfer or distribute a machine-readable copy to any other person, nor to have any other person type the programs into a computer on your behalf. We do not want to hear bug reports from you if you choose this option, because experience has shown that *virtually all* reported bugs in such cases are typing errors!
- You can download the Numerical Recipes programs electronically from the Numerical Recipes On-Line Software Store, located at our Web site (<http://www.nr.com>). They are packaged as a single compressed file, and you'll need to purchase a license to download and unpack them. Any number of single-screen licenses can be purchased instantly (with discount for multiple screens) from the On-Line Store, with fees that depend on your operating system (Windows or Macintosh versus Linux or UNIX) and whether you are affiliated with an educational institution. Purchasing a single-screen license is also the way to start if you want to acquire a more general (site or corporate) license; your single-screen cost will be subtracted from the cost of any later license upgrade.
- You can purchase media containing the programs from Cambridge University Press. A diskette version is available for Windows machines. CDROM versions in ISO-9660 format for Windows, Macintosh, and UNIX/Linux systems are also available; these include Fortran, C, and C++ versions on a single CDROM (as well as versions in Pascal and BASIC from the first edition). Diskettes purchased from Cambridge University Press include

a single-screen license for Windows only. The CDROM is available with a single-screen license for Windows or Macintosh (order ISBN 0 521 750350), or (at a slightly higher price) with a single-screen license for UNIX/Linux workstations (order ISBN 0 521 750369). Orders for media from Cambridge University Press can be placed at 800 872-7423 (North America only) or by email to orders@cup.org (North America) or directcustserv@cambridge.org (rest of world). Or, visit the Web site <http://www.cambridge.org>.

Types of License Offered

Here are the types of licenses that we offer. Note that some types are automatically acquired with the purchase of media from Cambridge University Press, or of an unlocking password from the Numerical Recipes On-Line Software Store, while other types of licenses require that you communicate specifically with Numerical Recipes Software (email: orders@nr.com or fax: 781 863-1739). Our Web site <http://www.nr.com> has additional information.

- [“Immediate License”] If you are the individual owner of a copy of this book and you type one or more of its routines into your computer, we authorize you to use them on that computer for your own personal and noncommercial purposes. You are not authorized to transfer or distribute machine-readable copies to any other person, or to use the routines on more than one machine, or to distribute executable programs containing our routines. This is the only free license.
- [“Single-Screen License”] This is the most common type of low-cost license, with terms governed by our Single Screen (Shrinkwrap) License document (complete terms available through our Web site). Basically, this license lets you use Numerical Recipes routines on any one screen (PC, workstation, X-terminal, etc.). You may also, under this license, transfer pre-compiled, executable programs incorporating our routines to other, unlicensed, screens or computers, providing that (i) your application is noncommercial (i.e., does not involve the selling of your program for a fee), (ii) the programs were first developed, compiled, and successfully run on a licensed screen, and (iii) our routines are bound into the programs in such a manner that they cannot be accessed as individual routines and cannot practicably be unbound and used in other programs. That is, under this license, your program user must not be able to use our programs as part of a program library or “mix-and-match” workbench. Conditions for other types of commercial or noncommercial distribution may be found on our Web site (<http://www.nr.com>).
- [“Multi-Screen, Server, Site, and Corporate Licenses”] The terms of the Single Screen License can be extended to designated groups of machines, defined by number of screens, number of machines, locations, or ownership. Significant discounts from the corresponding single-screen

prices are available when the estimated number of screens exceeds 40. Contact Numerical Recipes Software (email: orders@nr.com or fax: 781 863-1739) for details.

- [“Course Right-to-Copy License”] Instructors at accredited educational institutions who have adopted this book for a course, and who have already purchased a Single Screen License (either acquired with the purchase of media, or from the Numerical Recipes On-Line Software Store), may license the programs for use in that course as follows: Mail your name, title, and address; the course name, number, dates, and estimated enrollment; and advance payment of \$5 per (estimated) student to Numerical Recipes Software, at this address: P.O. Box 243, Cambridge, MA 02238 (USA). You will receive by return mail a license authorizing you to make copies of the programs for use by your students, and/or to transfer the programs to a machine accessible to your students (but only for the duration of the course).

About Copyrights on Computer Programs

Like artistic or literary compositions, computer programs are protected by copyright. Generally it is an infringement for you to copy into your computer a program from a copyrighted source. (It is also not a friendly thing to do, since it deprives the program’s author of compensation for his or her creative effort.) Under copyright law, all “derivative works” (modified versions, or translations into another computer language) also come under the same copyright as the original work.

Copyright does not protect ideas, but only the expression of those ideas in a particular form. In the case of a computer program, the ideas consist of the program’s methodology and algorithm, including the necessary sequence of steps adopted by the programmer. The expression of those ideas is the program source code (particularly any arbitrary or stylistic choices embodied in it), its derived object code, and any other derivative works.

If you analyze the ideas contained in a program, and then express those ideas in your own completely different implementation, then that new program implementation belongs to you. That is what we have done for those programs in this book that are not entirely of our own devising. When programs in this book are said to be “based” on programs published in copyright sources, we mean that the ideas are the same. The expression of these ideas as source code is our own. We believe that no material in this book infringes on an existing copyright.

Trademarks

Several registered trademarks appear within the text of this book: Sun is a trademark of Sun Microsystems, Inc. SPARC and SPARCstation are trademarks of SPARC International, Inc. Microsoft, Windows 95, Windows NT, PowerStation, and MS are trademarks of Microsoft Corporation. DEC, VMS, Alpha AXP, and ULTRIX are trademarks of Digital Equipment Corporation. IBM is a trademark of International Business Machines Corporation. Apple and Macintosh are trademarks of Apple Computer, Inc. UNIX is a trademark licensed exclusively through X/Open

Co. Ltd. IMSL is a trademark of Visual Numerics, Inc. NAG refers to proprietary computer software of Numerical Algorithms Group (USA) Inc. PostScript and Adobe Illustrator are trademarks of Adobe Systems Incorporated. Last, and no doubt least, Numerical Recipes (when identifying products) is a trademark of Numerical Recipes Software.

Attributions

The fact that ideas are legally “free as air” in no way supersedes the ethical requirement that ideas be credited to their known originators. When programs in this book are based on known sources, whether copyrighted or in the public domain, published or “handed-down,” we have attempted to give proper attribution. Unfortunately, the lineage of many programs in common circulation is often unclear. We would be grateful to readers for new or corrected information regarding attributions, which we will attempt to incorporate in subsequent printings.

Chapter 21. Introduction to Fortran 90 Language Features

21.0 Introduction

Fortran 90 is in many respects a backwards-compatible modernization of the long-used (and much abused) Fortran 77 language, but it is also, in other respects, a new language for parallel programming on present and future multiprocessor machines. These twin design goals of the language sometimes add confusion to the process of becoming fluent in Fortran 90 programming.

In a certain trivial sense, Fortran 90 is strictly backwards-compatible with Fortran 77. That is, any Fortran 90 compiler is supposed to be able to compile any legacy Fortran 77 code without error. The reason for terming this compatibility trivial, however, is that you have to tell the compiler (usually via a source file name ending in “.f” or “.for”) that it is dealing with a Fortran 77 file. If you instead try to pass off Fortran 77 code as native Fortran 90 (e.g., by naming the source file something ending in “.f90”) it will not always work correctly!

It is best, therefore, to approach Fortran 90 as a new computer language, albeit one with a lot in common with Fortran 77. Indeed, in such terms, Fortran 90 is a fairly *big* language, with a large number of new constructions and intrinsic functions. Here, in one short chapter, we do not pretend to provide a complete description of the language. Luckily, there are good books that do exactly that. Our favorite one is by Metcalf and Reid [1], cited throughout this chapter as “M&R.” Other good starting points include [2] and [3].

Our goal, in the remainder of this chapter, is to give a good, working description of those Fortran 90 language features that are not immediately self-explanatory to Fortran 77 programmers, with particular emphasis on those that occur most frequently in the Fortran 90 versions of the Numerical Recipes routines. This chapter, by itself, will not teach you to write Fortran 90 code. But it ought to help you acquire a reading knowledge of the language, and perhaps provide enough of a head start that you can rapidly pick up the rest of what you need to know from M&R or another Fortran 90 reference book.

21.1 Quick Start: Using the Fortran 90 Numerical Recipes Routines

This section is for people who want to jump right in. We'll compute a Bessel function $J_0(x)$, where x is equal to the fourth root of the Julian Day number of the 200th full moon since January 1900. (Now *there's* a useful quantity!)

First, locate the important files `nrtype.f90`, `nrutil.f90`, and `nr.f90`, as listed in Appendices C1, C1, and C2, respectively. These contain *modules* that either are (i) used by our routines, or else (ii) describe the calling conventions of our routines to (your) user programs. Compile each of these files, producing (with most compilers) a `.mod` file and a `.o` (or similarly named) file for each one.

Second, create this main program file:

```
PROGRAM hello_bessel
USE nrtype
USE nr, ONLY: flmoon, bessj0
IMPLICIT NONE
INTEGER(I4B) :: n=200,nph=2,jd
REAL(SP) :: x,frac,ans
call flmoon(n,nph,jd,frac)
x=jd**0.25_sp
ans=bessj0(x)
write (*,*) 'Hello, Bessel: ', ans
END PROGRAM
```

Here is a quick explanation of some elements of the above program:

The first `USE` statement includes a module of ours named `nrtype`, whose purpose is to give symbolic names to some kinds of data types, among them single-precision reals ("`sp`") and four-byte integers ("`i4b`"). The second `USE` statement includes a module of ours that defines the calling sequences, and variable types, expected by (in this case) the Numerical Recipes routines `flmoon` and `bessj0`.

The `IMPLICIT NONE` statement signals that we want the compiler to require us explicitly to declare all variable types. *We strongly urge that you always take this option.*

The next two lines declare integer and real variables of the desired kinds. The variable `n` is initialized to the value 200, `nph` to 2 (a value expected by `flmoon`).

We call `flmoon`, and take the fourth root of the answer it returns as `jd`. Note that the constant 0.25 is typed to be single-precision by the appended `_sp`.

We call the `bessj0` routine, and print the answer.

Third, compile the main program file, and also the files `flmoon.f90`, `bessj0.f90`. Then, link the resulting object files with also `nrutil.o` (or similar system-dependent name, as produced in step 1). Some compilers will also require you to link with `nr.o` and `nrtype.o`.

Fourth, run the resulting executable file. Typical output is:

```
Hello, Bessel: 7.3096365E-02
```

21.2 Fortran 90 Language Concepts

The Fortran 90 language standard defines and uses a number of standard terms for concepts that occur in the language. Here we summarize briefly some of the most important concepts. Standard Fortran 90 terms are shown in *italics*. While by no means complete, the information in this section should help you get a quick start with your favorite Fortran 90 reference book or language manual.

A note on capitalization: Outside a character context, Fortran 90 is not case-sensitive, so you can use upper and lower case any way you want, to improve readability. A variable like SP (see below) is the same variable as the variable sp. We like to capitalize keywords whose use is primarily at compile-time (statements that delimit program and subprogram boundaries, declaration statements of variables, fixed parameter values), and use lower case for the bulk of run-time code. You can adopt any convention that you find helpful to your own programming style; but we strongly urge you to adopt and follow *some* convention.

Data Types and Kinds

Data types (also called simply *types*) can be either *intrinsic data types* (the familiar INTEGER, REAL, LOGICAL, and so forth) or else *derived data types* that are built up in the manner of what are called “structures” or “records” in other computer languages. (We’ll use derived data types very sparingly in this book.) Intrinsic data types are further specified by their *kind parameter* (or simply *kind*), which is simply an integer. Thus, on many machines, REAL(4) (with *kind* = 4) is a single-precision real, while REAL(8) (with *kind* = 8) is a double-precision real. *Literal constants* (or simply *literals*) are specified as to kind by appending an underscore, as 1.5_4 for single precision, or 1.5_8 for double precision. [M&R, §2.5–§2.6]

Unfortunately, the specific integer values that define the different kind types are not specified by the language, but can vary from machine to machine. For that reason, one almost never uses literal kind parameters like 4 or 8, but rather defines in some central file, and imports into all one’s programs, symbolic names for the kinds. For this book, that central file is the *module* named *nrtype*, and the chosen symbolic names include SP, DP (for reals); I2B, I4B (for two- and four-byte integers); and LGT for the default logical type. You will therefore see us consistently writing REAL(SP), or 1.5_sp, and so forth.

Here is an example of declaring some variables, including a one-dimensional array of length 500, and a two-dimensional array with 100 rows and 200 columns:

```
USE nrtype
REAL(SP) :: x,y,z
INTEGER(I4B) :: i,j,k
REAL(SP), DIMENSION(500) :: arr
REAL(SP), DIMENSION(100,200) :: barr
REAL(SP) :: carr(500)
```

The last line shows an alternative form for array syntax. And yes, there *are* default kind parameters for each intrinsic type, but these vary from machine to machine and can get you into trouble when you try to move code. We therefore specify all kind parameters explicitly in almost all situations.

Array Shapes and Sizes

The *shape* of an array refers to both its dimensionality (called its *rank*), and also the lengths along each dimension (called the *extents*). The shape of an array is specified by a rank-one array whose elements are the extents along each dimension, and can be queried with the shape intrinsic (see p. 949). Thus, in the above example, `shape(barr)` returns an array of length 2 containing the values (100, 200).

The *size* of an array is its total number of elements, so the intrinsic `size(barr)` would return 20000 in the above example. More often one wants to know the extents along each dimension, separately: `size(barr,1)` returns the value 100, while `size(barr,2)` returns the value 200. [M&R, §2.10]

Section §21.3, below, discusses additional aspects of arrays in Fortran 90.

Memory Management

Fortran 90 is greatly superior to Fortran 77 in its memory-management capabilities, seen by the user as the ability to create, expand, or contract workspace for programs. Within *subprograms* (that is, *subroutines* and *functions*), one can have *automatic arrays* (or other *automatic data objects*) that come into existence each time the subprogram is entered, and disappear (returning their memory to the pool) when the subprogram is exited. The size of automatic objects can be specified by arbitrary expressions involving values passed as *actual arguments* in the calling program, and thus received by the subprogram through its corresponding *dummy arguments*. [M&R, §6.4]

Here is an example that creates some automatic workspace named `carr`:

```
SUBROUTINE dosomething(j,k)
  USE nrtype
  REAL(SP), DIMENSION(2*j,k**2) :: carr
```

Finer control on when workspace is created or destroyed can be achieved by declaring *allocatable arrays*, which exist as names only, without associated memory, until they are *allocated* within the program or subprogram. When no longer needed, they can be *deallocated*. The *allocation status* of an allocatable array can be tested by the program via the *allocated* intrinsic function (p. 952). [M&R, §6.5]

Here is an example in outline:

```
REAL(SP), DIMENSION(:,:), ALLOCATABLE :: darr
...
allocate(darr(10,20))
...
deallocate(darr)
...
allocate(darr(100,200))
...
deallocate(darr)
```

Notice that `darr` is originally declared with only “slots” (colons) for its dimensions, and is then allocated/deallocated twice, with different sizes.

Yet finer control is achieved by the use of *pointers*. Like an allocatable array, a pointer can be allocated, at will, its own associated memory. However, it has the additional flexibility of alternatively being *pointer associated* with a *target* that

already exists under another name. Thus, pointers can be used as redefinable aliases for other variables, arrays, or (see §21.3) *array sections*. [M&R, §6.12]

Here is an example that first associates the pointer `parr` with the array `earr`, then later cancels that association and allocates it its own storage of size 50:

```
REAL(SP), DIMENSION(:), POINTER :: parr
REAL(SP), DIMENSION(100), TARGET :: earr
...
parr => earr
...
nullify(parr)
allocate(parr(50))
...
deallocate(parr)
```

Procedure Interfaces

When a procedure is *referenced* (e.g., called) from within a program or subprogram (examples of *scoping units*), the scoping unit must be told, or must deduce, the procedure's *interface*, that is, its calling sequence, including the types and kinds of all dummy arguments, returned values, etc. The recommended procedure is to specify this interface via an *explicit interface*, usually an *interface block* (essentially a declaration statement for subprograms) in the calling subprogram or in some *module* that the calling program includes via a USE statement. In this book all interfaces are explicit, and the module named `nr` contains interface blocks for all of the Numerical Recipes routines. [M&R, §5.11]

Here is a typical example of an interface block:

```
INTERFACE
  SUBROUTINE caldat(julian,mm,id,iyyy)
  USE nrtype
  INTEGER(I4B), INTENT(IN) :: julian
  INTEGER(I4B), INTENT(OUT) :: mm,id,iyyy
  END SUBROUTINE caldat
END INTERFACE
```

Once this interface is made known to a program that you are writing (by either explicit inclusion or a USE statement), then the compiler is able to flag for you a variety of otherwise difficult-to-find bugs. Although interface blocks can sometimes seem overly wordy, they give a big payoff in ultimately minimizing programmer time and frustration.

For compatibility with Fortran 77, the language also allows for *implicit interfaces*, where the calling program tries to figure out the interface by the old rules of Fortran 77. These rules are quite limited, and prone to producing devilishly obscure program bugs. We strongly recommend that implicit interfaces never be used.

Elemental Procedures and Generic Interfaces

Many *intrinsic procedures* (those defined by the language standard and thus usable without any further definition or specification) are also *generic*. This means that a single procedure name, such as `log(x)`, can be used with a variety of types and kind parameters for the argument `x`, and the result returned will have the same type and kind parameter as the argument. In this example, `log(x)` allows any real or complex argument type.

Better yet, most generic functions are also *elemental*. The argument of an elemental function can be an array of arbitrary shape! Then, the returned result is an array of the same shape, with each element containing the result of applying the function to the corresponding element of the argument. (Hence the name *elemental*, meaning “applied element by element.”) [M&R, §8.1] For example:

```
REAL(SP), DIMENSION(100,100) :: a,b
b=sin(a)
```

Fortran 90 has no facility for creating new, user-defined elemental functions. It does have, however, the related facility of *overloading* by the use of *generic interfaces*. This is invoked by the use of an interface block that attaches a single *generic name* to a number of distinct subprograms whose dummy arguments have different types or kinds. Then, when the generic name is referenced (e.g., called), the compiler chooses the specific subprogram that matches the types and kinds of the actual arguments used. [M&R, §5.18] Here is an example of a generic interface block:

```
INTERFACE myfunc
  FUNCTION myfunc_single(x)
    USE nrtype
    REAL(SP) :: x,myfunc_single
  END FUNCTION myfunc_single

  FUNCTION myfunc_double(x)
    USE nrtype
    REAL(DP) :: x,myfunc_double
  END FUNCTION myfunc_double
END INTERFACE
```

A program with knowledge of this interface could then freely use the function reference `myfunc(x)` for `x`’s of both type `SP` and type `DP`.

We use overloading quite extensively in this book. A typical use is to provide, under the same name, both scalar and vector versions of a function such as a Bessel function, or to provide both single-precision and double-precision versions of procedures (as in the above example). Then, to the extent that we have provided all the versions that you need, you can pretend that our routine is elemental. In such a situation, if you ever call our function with a type or kind that we have *not* provided, the compiler will instantly flag the problem, because it is unable to resolve the generic interface.

Modules

Modules, already referred to several times above, are Fortran 90’s generalization of Fortran 77’s common blocks, INCLUDED files of parameter statements, and (to some extent) statement functions. Modules are *program units*, like main programs or subprograms (subroutines and functions), that can be separately compiled. A module is a convenient place to stash global data, *named constants* (what in Fortran 77 are called “symbolic constants” or “PARAMETERS”), interface blocks to subprograms and/or actual subprograms themselves (*module subprograms*). The convenience is that a module’s information can be incorporated into another program unit via a simple, one-line `USE` statement. [M&R, §5.5]

Here is an example of a simple module that defines a few parameters, creates some global storage for an array named `arr` (as might be done with a Fortran 77 common block), and defines the interface to a function `yourfunc`:

```

MODULE mymodule
  USE nrtype
  REAL(SP), PARAMETER :: con1=7.0_sp/3.0_sp, con2=10.0_sp
  INTEGER(I4B), PARAMETER :: ndim=10,mdim=9
  REAL(SP), DIMENSION(ndim,mdim) :: arr
  INTERFACE
    FUNCTION yourfunc(x)
      USE nrtype
      REAL(SP) :: x,yourfunc
    END FUNCTION yourfunc
  END INTERFACE
END MODULE mymodule

```

As mentioned earlier, the module `nr` contains `INTERFACE` declarations for all the Numerical Recipes. When we include a statement of the form

```
USE nr, ONLY: recipe1
```

it means that the program uses the additional routine `recipe1`. The compiler is able to use the explicit interface declaration in the module to check that `recipe1` is invoked with arguments of the correct type, shape, and number. However, a weakness of Fortran 90 is that there is no fail-safe way to be sure that the interface module (here `nr`) stays synchronized with the underlying routine (here `recipe1`). You might think that you could accomplish this by putting `USE nr, ONLY: recipe1` into the `recipe1` program itself. Unfortunately, the compiler interprets this as an erroneous double definition of `recipe1`'s interface, rather than (as would be desirable) as an opportunity for a consistency check. (To achieve this kind of consistency check, you can put the procedures themselves, not just their interfaces, into the module.)

21.3 More on Arrays and Array Sections

Arrays are the central conceptual core of Fortran 90 as a *parallel* programming language, and thus worthy of some further discussion. We have already seen that arrays can “come into existence” in Fortran 90 in several ways, either directly declared, as

```
REAL(SP), DIMENSION(100,200) :: arr
```

or else allocated by an *allocatable* variable or a *pointer* variable,

```

REAL(SP), DIMENSION(:,:), ALLOCATABLE :: arr
REAL(SP), DIMENSION(:,:), POINTER :: barr
...
allocate(arr(100,200),barr(100,200))

```

or else (not previously mentioned) passed into a subprogram through a dummy argument:

```

SUBROUTINE myroutine(carr)
  USE nrtype
  REAL(SP), DIMENSION(:,:) :: carr
  ...
  i=size(carr,1)

```

```
j=size(carr,2)
```

In the above example we also show how the subprogram can find out the size of the actual array that is passed, using the `size` intrinsic. This routine is an example of the use of an *assumed-shape array*, new to Fortran 90. The actual extents along each dimension are inherited from the calling routine at run time. A subroutine with assumed-shape array arguments *must* have an explicit interface in the calling routine, otherwise the compiler doesn't know about the extra information that must be passed. A typical setup for calling `myroutine` would be:

```
PROGRAM use_myroutine
USE nrtype
REAL(SP), DIMENSION(10,10) :: arr
INTERFACE
  SUBROUTINE myroutine(carr)
    USE nrtype
    REAL(SP), DIMENSION(:,:) :: carr
  END SUBROUTINE myroutine
END INTERFACE
...
call myroutine(a)
```

Of course, for the recipes we have provided all the interface blocks in the file `nr.f90`, and you need only a `USE nr` statement in your calling program.

Conformable Arrays

Two arrays are said to be *conformable* if their shapes are the same. Fortran 90 allows practically all operations among conformable arrays and elemental functions that are allowed for scalar variables. Thus, if `arr`, `barr`, and `carr` are mutually conformable, we can write,

```
arr=barr+cos(carr)+2.0_sp
```

and have the indicated operations performed, element by corresponding element, on the entire arrays. The above line also illustrates that a scalar (here the constant `2.0_sp`, but a scalar variable would also be fine) is deemed conformable with *any* array — it gets “expanded” to the shape of the rest of the expression that it is in. [M&R, §3.11]

In Fortran 90, as in Fortran 77, the default lower bound for an array subscript is 1; however, it can be made some other value at the time that the array is declared:

```
REAL(SP), DIMENSION(100,200) :: farr
REAL(SP), DIMENSION(0:99,0:199) :: garr
...
farr = 3.0_sp*garr + 1.0_sp
```

Notice that `farr` and `garr` are conformable, since they have the same shape, in this case (100,200). Also note that when they are used in an array expression, the operations are taken between the corresponding elements *of their shapes*, not necessarily the corresponding elements *of their indices*. [M&R, §3.10] In other words, one of the components evaluated is,

```
farr(1,1) = 3.0_sp*garr(0,0) + 1.0_sp
```

This illustrates a fundamental aspect of array (or data) parallelism in Fortran 90. Array constructions should *not* be thought of as merely abbreviations for do-loops

over indices, but rather as genuinely parallel operations on same-shaped objects, abstracted of their indices. This is why the standard makes no statement about the order in which the individual operations in an array expression are executed; they might in fact be carried out simultaneously, on parallel hardware.

By default, array expressions and assignments are performed for all elements of the same-shaped arrays referenced. This can be modified, however, by use of a *where* construction like this:

```
where (harr > 0.0_sp)
  farr = 3.0_sp*garr + 1.0_sp
end where
```

Here *harr* must also be conformable to *farr* and *garr*. Analogously with the Fortran *if*-statement, there is also a one-line form of the *where*-statement. There is also a *where ... elsewhere ... end where* form of the statement, analogous to *if ... else if ... end if*. A significant language limitation in Fortran 90 is that nested *where*-statements are not allowed. [M&R, §6.8]

Array Sections

Much of the versatility of Fortran 90's array facilities stems from the availability of *array sections*. An array section acts like an array, but its memory location, and thus the values of its elements, is actually a subset of the memory location of an already-declared array. Array sections are thus "windows into arrays," and they can appear on either the left side, or the right side, or both, of a replacement statement. Some examples will clarify these ideas.

Let us presume the declarations

```
REAL(SP), DIMENSION(100) :: arr
INTEGER(I4B), DIMENSION(6) :: iarr=(/11,22,33,44,55,66/)
```

Note that *iarr* is not only declared, it is also initialized by an *initialization expression* (a replacement for Fortran 77's *DATA* statement). [M&R, §7.5] Here are some array sections constructed from these arrays:

<i>Array Section</i>	<i>What It Means</i>
<code>arr(:)</code>	same as <code>arr</code>
<code>arr(1:100)</code>	same as <code>arr</code>
<code>arr(1:10)</code>	one-dimensional array containing first 10 elements of <code>arr</code>
<code>arr(51:100)</code>	one-dimensional array containing second half of <code>arr</code>
<code>arr(51:)</code>	same as <code>arr(51:100)</code>
<code>arr(10:1:-1)</code>	one-dimensional array containing first 10 elements of <code>arr</code> , but in <i>reverse order</i>
<code>arr((/10,99,1,6/))</code>	one-dimensional array containing elements 10, 99, 1, and 6 of <code>arr</code> , in that order
<code>arr(iarr)</code>	one-dimensional array containing elements 11, 22, 33, 44, 55, 66 of <code>arr</code> , in that order

Now let's try some array sections of the two-dimensional array

```
REAL(SP), DIMENSION(100,100) :: barr
```

Array Section	What It Means
<code>barr(:, :)</code>	same as <code>barr</code>
<code>barr(1:100,1:100)</code>	same as <code>barr</code>
<code>barr(7, :)</code>	one-dimensional array containing the 7th row of <code>barr</code>
<code>barr(7, 1:100)</code>	same as <code>barr(7, :)</code>
<code>barr(:, 7)</code>	one-dimensional array containing the 7th column of <code>barr</code>
<code>barr(21:30,71:90)</code>	two-dimensional array containing the sub-block of <code>barr</code> with the indicated ranges of indices; the shape of this array section is (10, 20)
<code>barr(100:1:-1,100:1:-1)</code>	two-dimensional array formed by flipping <code>barr</code> upside down and backwards
<code>barr(2:100:2,2:100:2)</code>	two-dimensional array of shape (50, 50) containing the elements of <code>barr</code> whose row and column indices are both even

Some terminology: A construction like `2:100:2`, above, is called a *subscript triplet*. Its integer pieces (which may be integer constants, or more general integer expressions) are called *lower*, *upper*, and *stride*. Any of the three may be omitted. An omitted stride defaults to the value 1. Notice that, if $(upper - lower)$ has a different sign from *stride*, then a subscript triplet defines an empty or *zero-length* array, e.g., `1:5:-1` or `10:1:1` (or its equivalent form, simply `10:1`). Zero-length arrays are not treated as errors in Fortran 90, but rather as “no-ops.” That is, no operation is performed in an expression or replacement statement among zero-length arrays. (This is essentially the same convention as in Fortran 77 for do-loop indices, which array expressions often replace.) [M&R, §6.10]

It is important to understand that array sections, when used in array expressions, match elements with other parts of the expression *according to shape*, not according to indices. (This is exactly the same principle that we applied, above, to arrays with subscript lower bounds different from the default value of 1.) One frequently exploits this feature in using array sections to carry out operations on arrays that access neighboring elements. For example,

```
carr(1:n-1,1:n-1) = barr(1:n-1,1:n-1)+barr(2:n,2:n)
```

constructs in the $(n-1) \times (n-1)$ matrix `carr` the sum of each of the corresponding elements in $n \times n$ `barr` added to its diagonally lower-right neighbor.

Pointers are often used as aliases for array sections, especially if the same array sections are used repeatedly. [M&R, §6.12] For example, with the setup

```
REAL(SP), DIMENSION(:, :), POINTER :: leftb, rightb
```

```
leftb=>barr(1:n-1,1:n-1)
rightb=>barr(2:n,2:n)
```

the statement above can be coded as

```
carr(1:n-1,1:n-1)=leftb+rightb
```

We should also mention that array sections, while powerful and concise, are sometimes not quite powerful enough. While any row or column of a matrix is easily accessible as an array section, there is no good way, in Fortran 90, to access (e.g.) the diagonal of a matrix, even though its elements are related by a linear progression in the Fortran storage order (by columns). These so-called *skew-sections* were much discussed by the Fortran 90 standards committee, but they were not implemented. We will see examples later in this volume of work-around programming tricks (none totally satisfactory) for this omission. (Fortran 95 corrects the omission; see §21.6.)

21.4 Fortran 90 Intrinsic Procedures

Much of Fortran 90's power, both for parallel programming and for its concise expression of algorithmic ideas, comes from its rich set of intrinsic procedures. These have the effect of making the language "large," hence harder to learn. However, effort spent on learning to use the intrinsics — particularly some of their more obscure, and more powerful, optional arguments — is often handsomely repaid.

This section summarizes the intrinsics that we find useful in numerical work. We omit, here, discussion of intrinsics whose exclusive use is for character and string manipulation. We intend only a summary, not a complete specification, which can be found in M&R's Chapter 8, or other reference books.

If you find the sheer number of new intrinsic procedures daunting, you might want to start with our list of the "top 10" (with the number of different Numerical Recipes routines that use each shown in parentheses): `size` (254), `sum` (44), `dot_product` (31), `merge` (27), `all` (25), `maxval` (23), `matmul` (19), `pack` (18), `any` (17), and `spread` (15). (Later, in Chapter 23, you can compare these numbers with our frequency of using the short utility functions that we define in a module named `nrutil` — several of which we think ought to have been included as Fortran 90 intrinsic procedures.)

The type, kind, and shape of the value returned by intrinsic functions will usually be clear from the short description that we give. As an additional hint (though not necessarily a precise description), we adopt the following codes:

<i>Hint</i>	<i>What It Means</i>
[Int]	an INTEGER kind type
[Real]	a REAL kind type
[Cmplx]	a COMPLEX kind type
[Num]	a numerical type and kind
[Lgcl]	a LOGICAL kind type
[Iarr]	a one-dimensional INTEGER array
[argTS]	same type and shape as the first argument
[argT]	same type as the first argument, but not necessarily the same shape

Numerical Elemental Functions

Little needs to be said about the numerical functions with identical counterparts in Fortran 77: `abs`, `acos`, `aimag`, `asin`, `atan`, `atan2`, `conjg`, `cos`, `cosh`, `dim`, `exp`, `log`, `log10`, `max`, `min`, `mod`, `sign`, `sin`, `sinh`, `sqrt`, `tan`, and `tanh`. In Fortran 90 these are all *elemental* functions, so that any plausible type, kind, and shape of argument may be used. Except for `aimag`, which returns a real type from a complex argument, these all return [argTS] (see table above).

Although Fortran 90 recognizes, for compatibility, Fortran 77's so-called *specific names* for these functions (e.g., `iabs`, `dabs`, and `cabs` for the generic `abs`), these are entirely superfluous and should be avoided.

Fortran 90 corrects some ambiguity (or at least inconvenience) in Fortran 77's `mod(a,p)` function, by introducing a new function `modulo(a,p)`. The functions are essentially identical for positive arguments, but for negative `a` and positive `p`, `modulo` gives results more compatible with one's mathematical expectation that the answer should always be in the positive range 0 to `p`. E.g., `modulo(11,5)=1`, and `modulo(-11,5)=4`. [M&R, §8.3.2]

Conversion and Truncation Elemental Functions

Fortran 90's conversion (or, in the language of C, casting) and truncation functions are generally modeled on their Fortran 77 antecedents, but with the addition of an optional second integer argument, `kind`, that determines the kind of the result. Note that, if `kind` is omitted, you get a default kind — not necessarily related to the kind of your argument. The kind of the argument is of course known to the compiler by its previous declaration. Functions in this category (see below for explanation of arguments in slanted type) are:

[Real] `aint(a,kind)`

Truncate to integer value, return as a real kind.

[Real] `anint(a,kind)`

Nearest whole number, return as a real kind.

[Cmplx] `cmplx(x,y,kind)`

Convert to complex kind. If *y* is omitted, it is taken to be 0.

[Int] `int(a,kind)`
 Convert to integer kind, truncating towards zero.

[Int] `nint(a,kind)`
 Convert to integer kind, choosing the nearest whole number.

[Real] `real(a,kind)`
 Convert to real kind.

[Lgcl] `logical(a,kind)`
 Convert one logical kind to another.

We must digress here to explain the use of *optional arguments* and *keywords* as Fortran 90 language features. [M&R, §5.13] When a routine (either intrinsic or user-defined) has arguments that are declared to be optional, then the dummy names given to them also become keywords that distinguish — independent of their position in a calling list — which argument is intended to be passed. (There are some additional rules about this that we will not try to summarize here.) In this section's tabular listings, we indicate optional arguments in intrinsic routines by printing them in smaller slanted type. For example, the intrinsic function

`eoshift(array,shift,boundary,dim)`

has two required arguments, `array` and `shift`, and two optional arguments, `boundary` and `dim`. Suppose we want to call this routine with the actual arguments `myarray`, `myshift`, and `mydim`, but omitting the argument in the `boundary` slot. We do this by the expression

`eoshift(myarray,myshift,dim=mydim)`

Conversely, if we wanted a `boundary` argument, but no `dim`, we might write

`eoshift(myarray,myshift,boundary=myboundary)`

It is always a good idea to use this kind of keyword construction when invoking optional arguments, even though the rules allow keywords to be omitted in some unambiguous cases. Now back to the lists of intrinsic routines.

A peculiarity of the `real` function derives from its use both as a type conversion and for extracting the real part of complex numbers (related, but not identical, usages): If the argument of `real` is complex, and `kind` is omitted, then the result *isn't* a default real kind, but rather *is* (as one generally would want) the `real` kind type corresponding to the kind type of the complex argument, that is, single-precision real for single-precision complex, double-precision for double-precision, and so on. [M&R, §8.3.1] We recommend *never* using `kind` when you intend to extract the real part of a complex, and *always* using `kind` when you intend conversion of a real or integer value to a particular kind of `REAL`. (Use of the deprecated function `dble` is not recommended.)

The last two conversion functions are the exception in that they *don't* allow a `kind` argument, but rather return default integer kinds. (The X3J3 standards committee has fixed this in Fortran 95.)

[Int] `ceiling(a)`
 Convert to integer, truncating towards more positive.

[Int] `floor(a)`
 Convert to integer, truncating towards more negative.

Reduction and Inquiry Functions on Arrays

These are mostly the so-called *transformational functions* that accept array arguments and return either scalar values or else arrays of lesser rank. [M&R, §8.11] With no optional arguments, such functions act on all the elements of their single array argument, regardless of its shape, and produce a scalar result. When the optional argument `dim` is specified, they instead act on all one-dimensional sections that span the dimension `dim`, producing an answer one rank lower than the first argument (that is, omitting the `dim` dimension from its shape). When the optional argument `mask` is specified, only the elements with a corresponding true value in `mask` are scanned.

[Lgcl] `all(mask, dim)`
 Returns true if all elements of `mask` are true, false otherwise.

[Lgcl] `any(mask, dim)`
 Returns true if any of the elements of `mask` are true, false otherwise.

[Int] `count(mask, dim)`
 Counts the true elements in `mask`.

[Num] `maxval(array, dim, mask)`
 Maximum value of the array elements.

[Num] `minval(array, dim, mask)`
 Minimum value of the array elements.

[Num] `product(array, dim, mask)`
 Product of the array elements.

[Int] `size(array, dim)`
 Size (total number of elements) of `array`, or its extent along dimension `dim`.

[Num] `sum(array, dim, mask)`
 Sum of the array elements.

The use of the `dim` argument can be confusing, so an example may be helpful. Suppose we have

$$\text{myarray} = \begin{bmatrix} 1 & 2 & 3 & 4 \\ 5 & 6 & 7 & 8 \\ 9 & 10 & 11 & 12 \end{bmatrix}$$

where, as always, the `i` index in `array(i, j)` numbers the rows while the `j` index numbers the columns. Then

$$\text{sum(myarray, dim=1)} = (15, 18, 21, 24)$$

that is, the `i` indices are “summed away” leaving only a `j` index on the result; while

$$\text{sum(myarray, dim=2)} = (10, 26, 42)$$

that is, the *j* indices are “summed away” leaving only an *i* index on the result. Of course we also have

`sum(myarray) = 78`

Two related functions return the location of particular elements in an array. The returned value is a one-dimensional integer array containing the respective subscript of the element along each dimension. Note that when the argument object is a *one*-dimensional array, the returned object is an integer *array of length 1*, not simply an integer. (Fortran 90 distinguishes between these.)

[Iarr] `maxloc(array,mask)`
 Location of the maximum value in an array.

[Iarr] `minloc(array,mask)`
 Location of the minimum value in an array.

Similarly returning a one-dimensional integer array are

[Iarr] `shape(array)`
 Returns the shape of array as a one-dimensional integer array.

[Iarr] `lbound(array,dim)`
 When *dim* is absent, returns an array of lower bounds for each dimension of subscripts of *array*. When *dim* is present, returns the value only for dimension *dim*, as a scalar.

[Iarr] `ubound(array,dim)`
 When *dim* is absent, returns an array of upper bounds for each dimension of subscripts of *array*. When *dim* is present, returns the value only for dimension *dim*, as a scalar.

Array Unary and Binary Functions

The most powerful array operations are simply built into the language as operators. All the usual arithmetic and logical operators (+, -, *, /, **, .not., .and., .or., .eqv., .neqv.) can be applied to arrays of arbitrary shape or (for the binary operators) between two arrays of the same shape, or between arrays and scalars. The types of the arrays must, of course, be appropriate to the operator used. The result in all cases is to perform the operation element by element on the arrays.

We also have the intrinsic functions,

[Num] `dot_product(veca,vecb)`
 Scalar dot product of two one-dimensional vectors *veca* and *vecb*.

[Num] `matmul(mata,matb)`
 Result of matrix-multiplying the two two-dimensional matrices *mata* and *matb*. The shapes have to be such as to allow matrix multiplication. Vectors (one-dimensional arrays) are additionally allowed as either the first or second argument, but not both; they are treated as row vectors in the first argument, and as column vectors in the second.

You might wonder how to form the *outer* product of two vectors, since `matmul` specifically excludes this case. (See §22.1 and §23.5 for answer.)

Array Manipulation Functions

These include many powerful features that a good Fortran 90 programmer should master.

[argTS] `cshift(array,shift,dim)`

If `dim` is omitted, it is taken to be 1. Returns the result of circularly left-shifting every one-dimensional section of `array` (in dimension `dim`) by `shift` (which may be negative). That is, for positive `shift`, values are moved to smaller subscript positions. Consult a Fortran 90 reference (e.g., [M&R, §8.13.5]) for the case where `shift` is an array.

[argTS] `merge(tsource,fsource,mask)`

Returns same shape object as `tsource` and `fsource` containing the former's components where `mask` is true, the latter's where it is false.

[argTS] `eoshift(array,shift,boundary,dim)`

If `dim` is omitted, it is taken to be 1. Returns the result of end-off left-shifting every one-dimensional section of `array` (in dimension `dim`) by `shift` (which may be negative). That is, for positive `shift`, values are moved to smaller subscript positions. If `boundary` is present as a scalar, it supplies elements to fill in the blanks; if it is not present, zero values are used. Consult a Fortran 90 reference (e.g., [M&R, §8.13.5]) for the case where `boundary` and/or `shift` is an array.

[argT] `pack(array,mask,vector)`

Returns a one-dimensional array containing the elements of `array` that pass the mask. Components of optional `vector` are used to pad out the result to the size of `vector` with specified values.

[argT] `reshape(source,shape,pad,order)`

Takes the elements of `source`, in normal Fortran order, and returns them (as many as will fit) as an array whose shape is specified by the one-dimensional integer array `shape`. If there is space remaining, then `pad` must be specified, and is used (as many sequential copies as necessary) to fill out the rest. For description of `order`, consult a Fortran 90 reference, e.g., [M&R, 8.13.3].

[argT] `spread(source,dim,ncopies)`

Returns an array whose rank is one greater than `source`, and whose `dim` dimension is of length `ncopies`. Each of the result's `ncopies` array sections having a fixed subscript in dimension `dim` is a copy of `source`. (That is, it spreads `source` into the `dim`th dimension.)

[argT] `transpose(matrix)`

Returns the transpose of `matrix`, which must be two-dimensional.

[argT] `unpack(vector,mask,field)`

Returns an array whose type is that of `vector`, but whose shape is that of `mask`. The components of `vector` are put, in order, into the positions where `mask` is true. Where `mask` is false, components of `field` (which may be a scalar or an array with the same shape as `mask`) are used instead.

Bitwise Functions

Most of the bitwise functions should be familiar to Fortran 77 programmers as longstanding standard extensions of that language. Note that the bit *positions* number from zero to one less than the value returned by the `bit_size` function. Also note that bit positions number *from right to left*. Except for `bit_size`, the following functions are all elemental.

- [Int] `bit_size(i)`
 Number of bits in the integer type of *i*.
- [Lgcl] `btest(i,pos)`
 True if bit position *pos* is 1, false otherwise.
- [Int] `iand(i,j)`
 Bitwise logical and.
- [Int] `ibclr(i,pos)`
 Returns *i* but with bit position *pos* set to zero.
- [Int] `ibits(i,pos,len)`
 Extracts *len* consecutive bits starting at position *pos* and puts them in the low bit positions of the returned value. (The high positions are zero.)
- [Int] `ibset(i,pos)`
 Returns *i* but with bit position *pos* set to 1.
- [Int] `ieor(i,j)`
 Bitwise exclusive or.
- [Int] `ior(i,j)`
 Bitwise logical or.
- [Int] `ishft(i,shift)`
 Bitwise left shift by *shift* (which may be negative) with zeros shifted in from the other end.
- [Int] `ishftc(i,shift)`
 Bitwise circularly left shift by *shift* (which may be negative).
- [Int] `not(i)`
 Bitwise logical complement.

Some Functions Relating to Numerical Representations

- [Real] `epsilon(x)`
 Smallest nonnegligible quantity relative to 1 in the numerical model of *x*.
- [Num] `huge(x)`
 Largest representable number in the numerical model of *x*.
- [Int] `kind(x)`

Returns the kind value for the numerical model of *x*.

[Real] `nearest(x,s)`

Real number nearest to *x* in the direction specified by the sign of *s*.

[Real] `tiny(x)`

Smallest positive number in the numerical model of *x*.

Other Intrinsic Procedures

[Lgcl] `present(a)`

True, within a subprogram, if an optional argument is actually present, otherwise false.

[Lgcl] `associated(pointer,target)`

True if *pointer* is associated with *target* or (if *target* is absent) with any target, otherwise false.

[Lgcl] `allocated(array)`

True if the allocatable array is allocated, otherwise false.

There are some pitfalls in using `associated` and `allocated`, having to do with arrays and pointers that can find themselves in *undefined* status [see §21.5, and also M&R, §3.3 and §6.5.1]. For example, pointers are always “born” in an undefined status, where the `associated` function returns unpredictable values.

For completeness, here is a list of Fortran 90’s intrinsic procedures not already mentioned:

Other Numerical Representation Functions: `digits`, `exponent`, `fraction`, `rrspacing`, `scale`, `set_exponent`, `spacing`, `maxexponent`, `minexponent`, `precision`, `radix`, `range`, `selected_int_kind`, `selected_real_kind`.

Lexical comparison: `lge`, `lgt`, `lle`, `llt`.

Character functions: `ichar`, `char`, `achar`, `iachar`, `index`, `adjustl`, `adjustr`, `len_trim`, `repeat`, `scan`, `trim`, `verify`.

Other: `mvbits`, `transfer`, `date_and_time`, `system_clock`, `random_seed`, `random_number`. (We will discuss random numbers in some detail in Chapter B7.)

21.5 Advanced Fortran 90 Topics

Pointers, Arrays, and Memory Management

One of the biggest improvements in Fortran 90 over Fortran 77 is in the handling of arrays, which are the cornerstone of many numerical algorithms. In this subsection we will take a closer look at how to use some of these new array features effectively. We will look at how to code certain commonly occurring elements of program design, and we will pay particular attention to avoiding “memory leaks,” where — usually inadvertently — we keep cumulatively allocating new storage for an array, every time some piece of code is invoked.

Let’s first review some of the rules for using allocatable arrays and pointers to arrays. Recall that a pointer is born with an undefined status. Its status changes to “associated” when you make it refer to a target, and to “disassociated” when you nullify the pointer. [M&R, §3.3] You can also use `nullify` on a newly born pointer to change its status from undefined to disassociated; this allows you to test the status with the `associated` inquiry function. [M&R, §6.5.4] (While many compilers will not produce a run-time error if you test an undefined pointer with `associated`, you can’t rely on this *laissez-faire* in your programming.)

The initial status of an allocatable array is “not currently allocated.” Its status changes to “allocated” when you give it storage with `allocate`, and back to “not currently allocated” when you use `deallocate`. [M&R, §6.5.1] You can test the status with the `allocated` inquiry function. Note that while you can also give a pointer fresh storage with `allocate`, you can’t test this with `allocated` — only `associated` is allowed with pointers. Note also that nullifying an allocated pointer leaves its associated storage in limbo. You must instead `deallocate`, which gives the pointer a testable “disassociated” status.

While allocating an array that is already allocated gives an error, you are allowed to allocate a pointer that already has a target. This breaks the old association, and could leave the old target inaccessible if there is no other pointer associated with it. [M&R, §6.5.2] Deallocating an array or pointer that has not been allocated is always an error.

Allocated arrays that are local to a subprogram acquire the “undefined” status on exit from the subprogram unless they have the `SAVE` attribute. (Again, not all compilers enforce this, but be warned!) Such undefined arrays cannot be referenced in any way, so you should explicitly deallocate all allocated arrays that are not saved before returning from a subprogram. [M&R, §6.5.1] The same rule applies to arrays declared in modules that are currently accessed only by the subprogram. While you can reference undefined pointers (e.g., by first nullifying them), it is good programming practice to deallocate explicitly any allocated pointers declared locally before leaving a subprogram or module.

Now let’s turn to using these features in programs. The simplest example is when we want to implement global storage of an array that needs to be accessed by two or more different routines, and we want the size of the array to be determined at run time. As mentioned earlier, we implement global storage with a `MODULE` rather than a `COMMON` block. (We ignore here the additional possibility of passing

global variables by having one routine `CONTAINED` within the other.) There are two good ways of handling the dynamical allocation in a `MODULE`. Method 1 uses an allocatable array:

```
MODULE a
  REAL(SP), DIMENSION(:), ALLOCATABLE :: x
END MODULE a

SUBROUTINE b(y)
  USE a
  REAL(SP), DIMENSION(:) :: y
  ...
  allocate(x(size(y)))
  ... [other routines using x called here] ...
END SUBROUTINE b
```

Here the global variable `x` gets assigned storage in subroutine `b` (in this case, the same as the length of `y`). The length of `y` is of course defined in the procedure that calls `b`. The array `x` is made available to any other subroutine called by `b` by including a `USE a` statement. The status of `x` can be checked with an `allocated` inquiry function on entry into either `b` or the other subroutine if necessary. As discussed above, you must be sure to `deallocate` `x` before returning from subroutine `b`. If you want `x` to retain its values between calls to `b`, you add the `SAVE` attribute to its declaration in `a`, and *don't* `deallocate` it on returning from `b`. (Alternatively, you could put a `USE a` in your main program, but we consider that bug-prone, since forgetting to do so can create all manner of difficult-to-diagnose havoc.) To avoid allocating `x` more than once, you test it on entry into `b`:

```
if (.not. allocated(x)) allocate(x(size(y)))
```

The second way to implement this type of global storage (Method 2) uses a pointer:

```
MODULE a
  REAL(SP), DIMENSION(:), POINTER :: x
END MODULE a

SUBROUTINE b(y)
  USE a
  REAL(SP), DIMENSION(:) :: y
  REAL(SP), DIMENSION(size(y)), TARGET :: xx
  ...
  x=>xx
  ... [other routines using x called here] ...
END SUBROUTINE b
```

Here the *automatic* array `xx` gets its temporary storage automatically on entry into `b`, and automatically gets `deallocated` on exit from `b`. [M&R, §6.4] The global pointer `x` can access this storage in any routine with a `USE a` that is called by `b`. You can check that things are in order in such a called routine by testing `x` with `associated`. If you are going to use `x` for some other purpose as well, you should `nullify` it on leaving `b` so that it doesn't have undefined status. Note that this implementation does not allow values to be saved between calls: You can't `SAVE` automatic arrays — that's not what they're for. You would have to `SAVE x` in the module, and `allocate` it in the subroutine instead of pointing it to a suitable automatic array. But this is essentially Method 1 with the added complication of using a pointer, so Method 1 is simpler when you want to save values. When you don't

need to save values between calls, we lean towards Method 2 over Method 1 because we like the automatic allocation and deallocation, but either method works fine.

An example of Method 1 (allocatable array) is in routine `rkdummy` on page 1297. An example of Method 1 with `SAVE` is in routine `pwtset` on p. 1265. Method 2 (pointer) shows up in routines `newt` (p. 1196), `broydn` (p. 1199), and `fitexy` (p. 1286). A variation is shown in routines `linmin` (p. 1211) and `dlinmin` (p. 1212): When the array that needs to be shared is an argument of one of the routines, Method 2 is better.

An extension of these ideas occurs if we allocate some storage for an array initially, but then might need to increase the size of the array later without losing the already-stored values. The function `reallocate` in our utility module `nrutil` will handle this for you, but it expects a pointer argument as in Method 2. Since no automatic arrays are used, you are free to `SAVE` the pointer if necessary. Here is a simple example of how to use `reallocate` to create a workspace array that is local to a subroutine:

```
SUBROUTINE a
  USE nrutil, ONLY : reallocate
  REAL(SP), DIMENSION(:), POINTER, SAVE :: wksp
  LOGICAL(LGT), SAVE :: init=.true.
  if (init) then
    init=.false.
    nullify(wksp)
    wksp=>reallocate(wksp,100)
  end if
  ...
  if (nterm > size(wksp)) wksp=>reallocate(wksp,2*size(wksp))
  ...
END SUBROUTINE a
```

Here the workspace is initially allocated a size of 100. If the number of elements used (`nterm`) ever exceeds the size of the workspace, the workspace is doubled. (In a realistic example, one would of course check that the doubled size is in fact big enough.) Fortran 90 experts can note that the `SAVE` on `init` is not strictly necessary: Any local variable that is initialized is automatically saved. [M&R, §7.5]

You can find similar examples of `reallocate` (with some further discussion) in `eulsum` (p. 1070), `hufenc` (p. 1348), and `arcode` (p. 1350). Examples of `reallocate` used with global variables in modules are in `odeint` (p. 1300) and `ran_state` (p. 1144).

Another situation where we have to use pointers and not allocatable arrays is when the storage is required for components of a derived type, which are not allowed to have the allocatable attribute. Examples are in `hufmak` (p. 1346) and `arcmak` (p. 1349).

Turning away from issues relating to global variables, we now consider several other important programming situations that are nicely handled with pointers. The first case is when we want a subroutine to return an array whose size is not known in advance. Since dummy arguments are not allocatable, we must use a pointer. Here is the basic construction:

```
SUBROUTINE a(x,nx)
  REAL(SP), DIMENSION(:), POINTER :: x
  INTEGER(I4B), INTENT(OUT) :: nx
  LOGICAL(LGT), SAVE :: init=.true.
  if (init) then
```

```

        init=.false.
        nullify(x)
    else
        if (associated(x)) deallocate(x)
    end if
    ...
    nx=...
    allocate(x(nx))
    x(1:nx)=...
END SUBROUTINE a

```

Since the length of *x* can be found from *size(x)*, it is not absolutely necessary to pass *nx* as an argument. Note the use of the initial logic to avoid memory leaks. If a higher-level subroutine wants to recover the memory associated with *x* from the last call to SUBROUTINE *a*, it can do so by first deallocating it, and then nullifying the pointer. Examples of this structure are in *zbrak* (p. 1184), *period* (p. 1258), and *fasper* (p. 1259). A related situation is where we want a function to return an array whose size is not predetermined, such as in *voltra* on (p. 1326). The discussion of *voltra* also explains the potential pitfalls of functions returning pointers to dynamically allocated arrays.

A final useful pointer construction enables us to set up a data structure that is essentially an array of arrays, independently allocatable on each part. We are not allowed to declare an array of pointers in Fortran 90, but we can do this indirectly by defining a derived type that consists of a pointer to the appropriate kind of array. [M&R, §6.11] We can then define a variable that is an allocatable array of the new type. For example,

```

TYPE ptr_to_arr
    REAL(SP), DIMENSION(:), POINTER :: arr
END TYPE
TYPE(ptr_to_arr), DIMENSION(:), ALLOCATABLE :: x
...
allocate(x(n))
...
do i=1,n
    allocate(x(i)%arr(m))
end do

```

sets up a set *x* of *n* arrays of length *m*. See also the example in *mglin* (p. 1334).

There is a potential problem with dynamical memory allocation that we should mention. The Fortran 90 standard does not require that the compiler perform “garbage collection,” that is, it is not required to recover deallocated memory into nice contiguous pieces for reuse. If you enter and exit a subroutine many times, and each time a large chunk of memory gets allocated and deallocated, you could run out of memory with a “dumb” compiler. You can often alleviate the problem by deallocating variables in the reverse order that you allocated them. This tends to keep a large contiguous piece of memory free at the top of the heap.

Scope, Visibility, and Data Hiding

An important principle of good programming practice is *modularization*, the idea that different parts of a program should be insulated from each other as much as possible. An important subcase of modularization is *data hiding*, the principle that actions carried out on variables in one part of the code should not be able to

affect the values of variables in other parts of the code. When it is necessary for one “island” of code to communicate with another, the communication should be through a well-defined interface that makes it obvious exactly what communication is taking place, and prevents any other interchange from occurring. Otherwise, different sections of code should not have access to variables that they don’t need.

The concept of data hiding extends not only to variables, but also to the names of procedures that manipulate the variables: A program for screen graphics might give the user access to a routine for drawing a circle, but it might “hide” the names (and methods of operation) of the primitive routines used for calculating the coordinates of the points on the circumference. Besides producing code that is easier to understand and to modify, data hiding prevents unintended side effects from producing hard-to-find errors.

In Fortran, the principal language construction that effects data hiding is the use of subroutines. If all subprograms were restricted to have no more than ten executable statements per routine, and to communicate between routines only by an explicit list of arguments, the number of programming errors might be greatly reduced! Unfortunately few tasks can be easily coded in this style. For this and other reasons, we think that too much procedurization is a bad thing; one wants to find the *right* amount. Fortunately Fortran 90 provides several additional tools to help with data hiding.

Global variables and routine names are important, but potentially dangerous, things. In Fortran 90, global variables are typically encapsulated in modules. Access is granted only to routines with an appropriate USE statement, and can be restricted to specific identifiers by the ONLY option. [M&R, §7.10] In addition, variable and routine names within the module can be designated as PUBLIC or PRIVATE (see, e.g., quad3d on p. 1065). [M&R, §7.6]

The other way global variables get communicated is by having one routine CONTAINED within another. [M&R, §5.6] This usage is potentially lethal, however, because *all* the outer routine’s variables are visible to the inner routine. You can try to control the problem somewhat by passing some variables back and forth as arguments of the inner routine, but that still doesn’t prevent inadvertent side effects. (The most common, and most stupid, is inadvertent reuse of variables named *i* or *j* in the CONTAINED routine.) Also, a long list of arguments reduces the convenience of using an internal routine in the first place. We advise that internal subprograms be used with caution, and only to carry out simple tasks.

There are some good ways to use CONTAINS, however. Several of our recipes have the following structure: A principal routine is invoked with several arguments. It calls a subsidiary routine, which needs to know some of the principal routine’s arguments, some global variables, and some values communicated directly as arguments to the subsidiary routine. In Fortran 77, we have usually coded this by passing the global variables in a COMMON block and all other variables as arguments to the subsidiary routine. If necessary, we copied the arguments of the primary routine before passing them to the subsidiary routine. In Fortran 90, there is a more elegant way of accomplishing this, as follows:

```
SUBROUTINE recipe(arg)
  REAL(SP) :: arg
  REAL(SP) :: global_var
  call recipe_private
CONTAINS
```

```

SUBROUTINE recipe_private
...
call subsidiary(local_arg)
...
END SUBROUTINE recipe_private

SUBROUTINE subsidiary(local_arg)
...
END SUBROUTINE subsidiary
END SUBROUTINE recipe

```

Notice that the principal routine (`recipe`) has practically nothing in it — only declarations of variables intended to be visible to the subsidiary routine (`subsidiary`). All the real work of `recipe` is done in `recipe_private`. This latter routine has visibility on all of `recipe`'s variables, while any additional variables that `recipe_private` defines are *not* visible to `subsidiary` — which is the whole purpose of this way of organizing things. Obviously `arg` and `global_var` can be much more general data types than the example shown here, including function names. For examples of this construction, see `amoeba` (p. 1208), `amebsa` (p. 1222), `mrqmin` (p. 1292), and `medfit` (p. 1294).

Recursion

A subprogram is recursive if it calls itself. While forbidden in Fortran 77, recursion is allowed in Fortran 90. [M&R, §5.16–§5.17] You must supply the keyword `RECURSIVE` in front of the `FUNCTION` or `SUBROUTINE` keyword. In addition, if a `FUNCTION` calls itself directly, as opposed to calling another subprogram that in turn calls it, you must supply a variable to hold the result with the `RESULT` keyword. Typical syntax for this case is:

```

RECURSIVE FUNCTION f(x) RESULT(g)
REAL(SP) :: x,g
if ...
  g=...
else
  g=f(...)
end if
END FUNCTION f

```

When a function calls itself directly, as in this example, there always has to be a “base case” that does not call the function; otherwise the recursion never terminates. We have indicated this schematically with the `if...else...end if` structure.

On serial machines we tend to avoid recursive implementations because of the additional overhead they incur at execution time. Occasionally there are algorithms for which the recursion overhead is relatively small, and the recursive implementation is simpler than an iterative version. Examples in this book are `quad_3d` (p. 1065), `miser` (p. 1164), and `mglin` (p. 1334). Recursion is much more important when parallelization is the goal. We will encounter in Chapter 22 numerous examples of algorithms that can be parallelized with recursion.

SAVE Usage Style

A quirk of Fortran 90 is that any variable with initial values acquires the `SAVE` attribute automatically. [M&R, §7.5 and §7.9] As a help to understanding

an algorithm, we have elected to put an explicit `SAVE` on all variables that really do need to retain their values between calls to a routine. We do this even if it is redundant because the variables are initialized. Note that we generally prefer to assign initial values with initialization expressions rather than with `DATA` statements. We reserve `DATA` statements for cases where it is convenient to use the repeat count feature to set multiple occurrences of a value, or when binary, octal, or hexadecimal constants are used. [M&R, §2.6.1]

Named Control Structures

Fortran 90 allows control structures such as `do` loops and `if` blocks to be named. [M&R, §4.3–§4.5] Typical syntax is

```
name:do i=1,n
    ...
end do name
```

One use of naming control structures is to improve readability of the code, especially when there are many levels of nested loops and `if` blocks. A more important use is to allow `exit` and `cycle` statements, which normally refer to the innermost `do` loop in which they are contained, to transfer execution to the end of some outer loop. This is effected by adding the name of the outer loop to the statement: `exit name` or `cycle name`.

There is great potential for misuse with named control structures, since they share some features of the much-maligned `goto`. We recommend that you use them sparingly. For a good example of their use, contrast the Fortran 77 version of `simplx` with the Fortran 90 version on p. 1216.

21.6 And Coming Soon: Fortran 95

One of the more positive effects of Fortran 90's long gestation period has been the general recognition, both by the X3J3 committee and by the community at large, that Fortran needs to evolve over time. Indeed, as we write, the process of bringing forth a minor, but by no means insignificant, updating of Fortran 90 — named Fortran 95 — is well under way.

Fortran 95 will differ from Fortran 90 in about a dozen features, only a handful of which are of any importance to this book. Generally these are extensions that will make programming, especially parallel programming, easier. In this section we give a summary of the anticipated language changes. In §22.1 and §22.5 we will comment further on the implications of Fortran 95 to some parallel programming tasks; in §23.7 we comment on what differences Fortran 95 will make to our `nrutil` utility functions.

No programs in Chapters B1 through B20 of this book edition use any Fortran 95 extensions.

FORALL Statements and Blocks

Fortran 95 introduces a new `forall` control structure, somewhat akin to the `where` construct, but allowing for greater flexibility. It is something like a `do-loop`, but with the proviso that the indices looped over are allowed to be done in any order (ideally, in parallel). The `forall` construction comes in both single-statement and block variants. Instead of using the `do-loop`'s comma-separated triplets of lower-value, upper-value, and increment, it borrows its syntax from the colon-separated form of array sections. Some examples will give you the idea.

Here is a simple example that could alternatively be done with Fortran 90's array sections and `transpose` intrinsic:

```
forall (i=1:20, j=1:10:2) x(i,j)=y(j,i)
```

The block form allows more than one executable statement:

```
forall (i=1:20, j=1:10:2)
  x(i,j)=y(j,i)
  z(i,j)=y(i,j)**2
end forall
```

Here is an example that cannot be done with Fortran 90 array sections:

```
forall (i=1:20, j=1:20) a(i,j)=3*i+j**2
```

`forall` statements can also take optional masks that restrict their action to a subset of the loop index combinations:

```
forall (i=1:100, j=1:100, (i>=j .and. x(i,j)/=0.0) ) x(i,j)=1.0/x(i,j)
```

`forall` constructions can be nested, or nested inside `where` blocks, or have `where` constructions inside them. An additional new feature in Fortran 95 is that `where` blocks can themselves be nested.

PURE Procedures

Because the inside iteration of a `forall` block can be done in any order, or in parallel, there is a logical difficulty in allowing functions or subroutines inside such blocks: If the function or subroutine has *side effects* (that is, if it changes any data elsewhere in the machine, or in its own saved variables) then the result of a `forall` calculation could depend on the order in which the iterations happen to be done. This can't be tolerated, of course; hence a new `PURE` attribute for subprograms.

While the exact stipulations are somewhat technical, the basic idea is that if you declare a function or subroutine as `PURE`, with a syntax like,

```
PURE FUNCTION myfunc(x,y,z)
OR
PURE SUBROUTINE mysub(x,y,z)
```

then you are guaranteeing to the compiler (and it will enforce) that the only values changed by `mysub` or `myfunc` are returned function values, subroutine arguments with the `INTENT(OUT)` attribute, and automatic (scratch) variables within the procedure.

You can then use your pure procedures within `forall` constructions. Pure functions are also allowed in some specification statements.

ELEMENTAL Procedures

Fortran 95 removes Fortran 90's nagging restriction that only intrinsic functions are elemental. The way this works is that you write a pure procedure that operates on scalar values, but include the attribute `ELEMENTAL` (which automatically implies `PURE`). Then, as long as the function has an explicit interface in the referencing program, you can call it with any shape of argument, and it will act elementally. Here's an example:

```
ELEMENTAL FUNCTION myfunc(x,y,z)
REAL :: x,y,z,myfunc
...
myfunc = ...
END
```

In a program with an explicit interface for `myfunc` you could now have

```
REAL, DIMENSION(10,20) :: x,y,z,w
...
w=myfunc(x,y,z)
```

Pointer and Allocatable Improvements

Fortran 95, unlike Fortran 90, requires that any allocatable variables (except those with `SAVE` attributes) that are allocated within a subprogram be automatically deallocated by the compiler when the subprogram is exited. This will remove Fortran 90's "undefined allocation status" bugaboo.

Fortran 95 also provides a method for pointer variables to be born with disassociated association status, instead of the default (and often inconvenient) "undefined" status. The syntax is to add an initializing `=> NULL()` to the declaration, as:

```
REAL, DIMENSION(:,:), POINTER :: mypoint => NULL()
```

This does not, however, eliminate the possibility of undefined association status, because you have to remember to use the null initializer if want your pointer to be disassociated.

Some Other Fortran 95 Features

In Fortran 95, `maxloc` and `minloc` have the additional optional argument `DIM`, which causes them to act on all one-dimensional sections that span through the named dimension. This provides a means for getting the locations of the values returned by the corresponding functions `maxval` and `minval` in the case that their `DIM` argument is present.

The `sign` intrinsic can now distinguish a negative from a positive real zero value: `sign(2.0,-0.0)` is `-2.0`.

There is a new intrinsic subroutine `cpu_time(time)` that returns as a real value `time` a process's elapsed CPU time.

There are some minor changes in the namelist facility, in defining minimum field widths for the `I`, `B`, `O`, `Z`, and `F` edit descriptors, and in resolving minor conflicts with some other standards.

Chapter 22. Introduction to Parallel Programming

22.0 *Why Think Parallel?*

In recent years we Numerical Recipes authors have increasingly become convinced that a certain revolution, cryptically denoted by the words “parallel programming,” is about to burst forth from its gestation and adolescence in the community of supercomputer users, and become the mainstream methodology for all computing.

Let’s review the past: Take a screwdriver and open up the computer (workstation or PC) that sits on your desk. (Don’t blame us if this voids your warranty; and be sure to unplug it first!) Count the integrated circuits — just the bigger ones, with more than a million gates (transistors). As we write, in 1995, even lowly memory chips have one or four million gates, and this number will increase rapidly in coming years. You’ll probably count at least dozens, and often hundreds, of such chips in your computer.

Next ask, how many of these chips are CPUs? That is, how many implement von Neumann processors capable of executing arbitrary, stored program code? For most computers, in 1995, the answer is: about one. A significant number of computers do have secondary processors that offload input-output and/or video functions. So, two or three is often a more accurate answer, but only one is usually under the user’s direct control.

Why do our desktop computers have dozens or hundreds of memory chips, but most often only one (user-accessible) CPU? Do CPU chips intrinsically cost more to manufacture? No. Are CPU chips more expensive than memory chips? Yes, primarily because fixed development and design costs must be distributed over a smaller number of units sold. We have been in a kind of economic equilibrium: CPU’s are relatively expensive because there is only one per computer; and there is only one per computer, because they are relatively expensive.

Stabilizing this equilibrium has been the fact that there has been no standard, or widely taught, methodology for parallel programming. Except for the special case of scientific computing on supercomputers (where large problems often have a regular or geometric character), it is not too much of an exaggeration to say that nobody *really knows how* to program multiprocessor machines. Symmetric multiprocessor

operating systems, for example, have been very slow in developing; and efficient, parallel methodologies for query-serving on large databases are even now a subject of continuing research.

However, things are now changing. We consider it an easy prognostication that, by the first years of the new century, the typical desktop computer will have 4 to 8 user-accessible CPUs; ten years after that, the typical number will be between 16 and 512. It is not coincidence that these numbers are characteristic of supercomputers (including some quite different architectures) in 1995. The rough rule of ten years' lag from supercomputer to desktop has held firm for quite some time now.

Scientists and engineers have the advantage that techniques for parallel computation in their disciplines *have* already been developed. With multiprocessor workstations right around the corner, we think that now is the right time for scientists and engineers who use computers to start *thinking parallel*. We don't mean that you should put an axe through the screen of your fast serial (single-CPU) workstation. We do mean, however, that you should start programming somewhat differently on that workstation, indeed, start thinking a bit differently about the way that you approach numerical problems in general.

In this volume of *Numerical Recipes in Fortran*, our pedagogical goal is to show you that there are conceptual and practical benefits in parallel thinking, even if you are using a serial machine today. These benefits include conciseness and clarity of code, reusability of code in wider contexts, and (not insignificantly) increased portability of code to today's parallel supercomputers. Of course, on parallel machines, either supercomputers today or desktop machines tomorrow, the benefits of thinking parallel are much more tangible: They translate into significant improvements in efficiency and computational capability.

Thinking Parallel with Fortran 90

Until very recently, a strong inhibition to thinking parallel was the lack of any standard, architecture-independent, computer language in which to think. That has changed with the finalization of the Fortran 90 language standard, and with the availability of good, optimizing Fortran 90 compilers on a variety of platforms.

There is a significant body of opinion (with which we, however, disagree) that there is no such thing as architecture-independent parallel programming. Proponents of this view, who are generally committed wizards at programming on one or another particular architecture, point to the fact that algorithms that are optimized to one architecture can run hundreds of times more slowly on other architectures. And, they are correct!

Our opposing point of view is one of pragmatism. We think that it is not hard to learn, in a general way, what kinds of architectures are in general use, and what kinds of parallel constructions work well (or poorly) on each kind. With this knowledge (much of which we hope to develop in this book) the user can, we think, write good, general-purpose parallel code that works on a variety of architectures — including, importantly, on purely serial machines. Equally important, the user will be aware of when certain parts of a code can be significantly improved on some, but not other, architectures.

Fortran 90 is a good test-bench for this point of view. It is not the perfect language for parallel programming. But it is *a* language, and it is the only

cross-platform *standard* language now available. The committee that developed the language between 1978 and 1991 (known technically as X3J3) had strong representation from both a traditional “vectorization” viewpoint (e.g., from the Cray XMP and YMP series of computers), and also from the “data parallel” or “SIMD” viewpoints of parallel machines like the CM-2 and CM-5 from Thinking Machines, Inc. Language compromises were made, and a few (in our view) almost essential features were left out (see §22.5). But, by and large, the necessary tools are there: If you learn to think parallel in Fortran 90, you will easily be able to transfer the skill to future parallel standards, whether they are Fortran-based, C-based, or other.

22.1 Fortran 90 Data Parallelism: Arrays and Ininsics

The underlying model for parallel computation in Fortran 90 is *data parallelism*, implemented by the use of arrays of data, and by the provision of operations and intrinsic functions that act on those arrays in parallel, in a manner optimized by the compiler for each particular hardware architecture. We will not try to draw a fine definitional distinction between “data parallelism” and so-called SIMD (single instruction multiple data) programming. For our purposes the two terms mean about the same thing: The programmer writes a single operation, “+” say, and the compiler causes it to be carried out on multiple pieces of data in as parallel a manner as the underlying hardware allows.

Any kind of parallel computing that is not SIMD is generally called MIMD (multiple instruction multiple data). A parallel programming language with MIMD features might allow, for example, several different subroutines — acting on different parts of the data — to be called into execution simultaneously. Fortran 90 has few, if any, MIMD constructions. A Fortran 90 compiler might, on some machines, execute MIMD code in implementing some Fortran 90 intrinsic functions (pack or unpack, e.g.), but this will be hidden from the Fortran 90 user. Some extensions of Fortran 90, like HPF, do implement MIMD features explicitly; but we will not consider these in this book. Fortran 95’s `forall` and `PURE` extensions (see §21.6) will allow some significantly greater access to MIMD features (see §22.5).

Array Parallel Operations

We have already met the most basic, and most important, parallel facility of Fortran 90, namely, the ability to use whole arrays in expressions and assignments, with the indicated operations being effected in parallel across the array. Suppose, for example, we have the two-dimensional matrices *a*, *b*, and *c*,

```
REAL, DIMENSION(30,30) :: a,b,c
```

Then, instead of the serial construction,

```
do j=1,30
  do k=1,30
    c(j,k)=a(j,k)+b(j,k)
  end do
end do
```

which is of course perfectly valid Fortran 90 code, we can simply write

```
c=a+b
```

The compiler deduces from the declaration statement that *a*, *b*, and *c* are matrices, and what their bounding dimensions are.

Let us dwell for a moment on the conceptual differences between the serial code and parallel code for the above matrix addition. Although one is perhaps used to seeing the nested do-loops as simply an idiom for “do-the-enclosed-on-all-components,” it in fact, according to the rules of Fortran, specifies a very particular time-ordering for the desired operations. The matrix elements are added by rows, in order (*j*=1, 30), and within each row, by columns, in order (*k*=1, 30).

In fact, the serial code above *overspecifies* the desired task, since it is guaranteed by the laws of mathematics that the order in which the element operations are done is of no possible relevance. Over the 50 year lifetime of serial von Neuman computers, we programmers have been brainwashed to break up all problems into single executable streams *in the time dimension only*. Indeed, the major design problem for supercomputer compilers for the last 20 years has been to *undo* such serial constructions and recover the underlying “parallel thoughts,” for execution in vector or parallel processors. Now, rather than taking this expensive detour into and out of serial-land, we are asked simply to say what we mean in the first place, *c=a+b*.

The essence of parallel programming is *not* to force “into the time dimension” (i.e., to serialize) operations that naturally extend across a span of data, that is, “in the space dimension.” If it were not for 50-year-old collective habits, and the languages designed to support them, parallel programming would probably strike us as more natural than its serial counterpart.

Broadcasts and Dimensional Expansion: SSP vs. MMP

We have previously mentioned the Fortran 90 rule that a scalar variable is conformable with any shape array. Thus, we can implement a calculation such as

$$y_i = x_i + s, \quad i = 1, \dots, n \quad (22.1.1)$$

with code like

```
y=x+s
```

where we of course assume previous declarations like

```
REAL(SP) :: s
REAL(SP), DIMENSION(n) :: x,y
```

with *n* a compile-time constant or dummy argument. (Hereafter, we will omit the declarations in examples that are this simple.)

This seemingly simple construction actually hides an important underlying parallel capability, namely, that of *broadcast*. The sums in *y=x+s* are done in parallel

on different CPUs, each CPU accessing different components of x and y . Yet, they all must access the same scalar value s . If the hardware has local memory for each CPU, the value of s must be replicated and transferred to each CPU's local memory. On the other hand, if the hardware implements a single, global memory space, it is vital to do something that mitigates the traffic jam potentially caused by all the CPUs trying to access the same memory location at the same time. (We will use the term "broadcast" to refer equally to both cases.) Although hidden from the user, Fortran 90's ability to do broadcasts is an essential feature of it as a parallel language.

Broadcasts can be more complicated than the above simple example. Consider, for example, the calculation

$$w_i = \sum_{j=1}^n |x_i + x_j|, \quad i = 1, \dots, n \quad (22.1.2)$$

Here, we are doing n^2 operations: For each of n values of i there is a sum over n values of j .

Serial code for this calculation might be

```
do i=1,n
  w(i)=0.
  do j=1,n
    w(i)=w(i)+abs(x(i)+x(j))
  end do
end do
```

The obvious immediate parallelization in Fortran 90 uses the `sum` intrinsic function to eliminate the inner do-loop. This would be a suitable amount of parallelization for a small-scale parallel machine, with a few processors:

```
do i=1,n
  w(i)=sum(abs(x(i)+x))
end do
```

Notice that the conformability rule implies that a new value of $x(i)$, a scalar, is being broadcast to all the processors involved in the `abs` and `sum`, with each iteration of the loop over i .

What about the outer do-loop? Do we need, or want, to eliminate it, too? That depends on the architecture of your computer, and on the tradeoff between time and memory in your problem (a common feature of all computing, no less so parallel computing). Here is an implementation that is free of all do-loops, in principle capable of being executed in a small number (independent of n) of parallel operations:

```
REAL(SP), DIMENSION(n,n) :: a
...
a = spread(x,dim=2,ncopies=n)+spread(x,dim=1,ncopies=n)
w = sum(abs(a),dim=1)
```

This is an example of what we call *dimensional expansion*, as implemented by the `spread` intrinsic. Although the above may strike you initially as quite a cryptic construction, it is easy to learn to read it. In the first assignment line, a matrix is constructed with all possible values of $x(i)+x(j)$. In the second assignment line, this matrix is collapsed back to a vector by applying the `sum` operation to the absolute value of its elements, across one of its dimensions.

More explicitly, the first line creates a matrix *a* by adding two matrices each constructed via `spread`. In `spread`, the `dim` argument specifies which argument is *duplicated*, so that the first term *varies* across its first (row) dimension, and vice versa for the second term:

$$a_{ij} = x_i + x_j$$

$$= \begin{pmatrix} x_1 & x_1 & x_1 & \dots \\ x_2 & x_2 & x_2 & \dots \\ x_3 & x_3 & x_3 & \dots \\ \vdots & \vdots & \vdots & \ddots \end{pmatrix} + \begin{pmatrix} x_1 & x_2 & x_3 & \dots \\ x_1 & x_2 & x_3 & \dots \\ x_1 & x_2 & x_3 & \dots \\ \vdots & \vdots & \vdots & \ddots \end{pmatrix} \quad (22.1.3)$$

Since equation (22.1.2) above is symmetric in *i* and *j*, it doesn't really matter what value of `dim` we put in the `sum` construction, but the value `dim=1` corresponds to summing across the rows, that is, down each column of equation (22.1.3).

Be sure that you understand that the `spread` construction changed an $O(n)$ memory requirement into an $O(n^2)$ one! If your values of *n* are large, this is an impossible burden, and the previous implementation with a single `do-loop` remains the only practical one. On the other hand, if you are working on a massively parallel machine, whose number of processors is comparable to n^2 (or at least much larger than *n*), then the `spread` construction, and the underlying broadcast capability that it invokes, leads to a big win: All n^2 operations can be done in parallel. This distinction between small-scale parallel machines — which we will hereafter refer to as *SSP machines* — and massively multiprocessor machines — which we will refer to as *MMP machines* — is an important one. A main goal of parallelism is to saturate the available number of processors, and algorithms for doing so are often different in the SSP and MMP opposite limits. Dimensional expansion is one method for saturating processors in the MMP case.

Masks and “Index Loss”

An instructive extension of the above example is the following case of a product that omits one term (the diagonal one):

$$w_i = \prod_{\substack{j=1 \\ j \neq i}}^n (x_j - x_i), \quad i = 1, \dots, n \quad (22.1.4)$$

Formulas like equation (22.1.4) frequently occur in the context of interpolation, where all the x_i 's are known to be distinct, so let us for the moment assume that this is the case.

Serial code for equation (22.1.4) could be

```
do i=1,n
  w(i)=1.0_sp
  do j=1,n
    if (j /= i) w(i)=w(i)*(x(j)-x(i))
  end do
end do
```

Parallel code for SSP machines, or for large enough *n* on MMP machines, could be

```

do i=1,n
  w(i)=product( x-x(i), mask=(x/=x(i)) )
end do

```

Here, the mask argument in the product intrinsic function causes the diagonal term to be omitted from the product, as we desire. There are some features of this code, however, that bear commenting on.

First, notice that, according to the rules of conformability, the expression $x/=x(i)$ broadcasts the scalar $x(i)$ and generates a logical array of length n , suitable for use as a mask in the product intrinsic. It is quite common in Fortran 90 to generate masks “on the fly” in this way, particularly if the mask is to be used only once.

Second, notice that the j index has disappeared completely. It is now implicit in the two occurrences of x (equivalent to $x(1:n)$) on the right-hand side. With the disappearance of the j index, we also lose the ability to do the test on i and j , but must use, in essence, $x(i)$ and $x(j)$ instead! That is a very general feature in Fortran 90: when an operation is done in parallel across an array, there is *no associated index* available within the operation. This “index loss,” as we will see in later discussion, can sometimes be quite an annoyance.

A language construction present in CM [Connection Machine] Fortran, the so-called `forall`, which would have allowed access to an associated index in many cases, was eliminated from Fortran 90 by the X3J3 committee, in a controversial decision. Such a construction will come into the language in Fortran 95.

What about code for an MMP machine, where we are willing to use dimensional expansion to achieve greater parallelism? Here, we can write,

```

a = spread(x,dim=2,ncopies=n)-spread(x,dim=1,ncopies=n)
w = product(a,dim=1,mask=(a/=0.))

```

This time it does matter that the value of `dim` in the product intrinsic is 1 rather than 2. If you write out the analog of equation (22.1.3) for the present example, you’ll see that the above fragment is the right way around. The problem of index loss is still with us: we have to construct a mask from the array a , not from its indices, *both* of which are now lost to us!

In most cases, there are workarounds (more, or less, awkward as they may be) for the problem of index loss. In the worst cases, which are quite rare, you have to create objects to hold, and thus bring back into play, the lost indices. For example,

```

INTEGER(I4B), DIMENSION(n) :: jj
...
jj = (/ (i,i=1,n) /)
do i=1,n
  w(i)=product( x-x(i), mask=(jj/=i) )
end do

```

Now the array `jj` is filled with the “lost” j index, so that it is available for use in the mask. A similar technique, involving spreads of `jj`, can be used in the above MMP code fragment, which used dimensional expansion. (Fortran 95’s `forall` construction will make index loss much less of a problem. See §21.6.)

Incidentally, the above Fortran 90 construction, `(/ (i,i=1,n) /)`, is called an *array constructor with implied do list*. For reasons to be explained in §22.2, we almost never use this construction, in most cases substituting a Numerical Recipes utility function for generating arithmetical progressions, which we call `arth`.

Interprocessor Communication Costs

It is both a blessing and a curse that Fortran 90 completely hides from the user the underlying machinery of interprocessor communication, that is, the way that data values computed by (or stored locally near) one CPU make their way to a different CPU that might need them next. The blessing is that, by and large, the Fortran 90 programmer need not be concerned with how this machinery works. If you write

```
a(1:10,1:10) = b(1:10,1:10) + c(10:1:-1,10:1:-1)
```

the required upside-down-and-backwards values of the array *c* are just *there*, no matter that a great deal of routing and switching may have taken place. An ancillary blessing is that this book, unlike so many other (more highly technical) books on parallel programming (see references below) need not be filled with complex and subtle discussions of CPU connectivity, topology, routing algorithms, and so on.

The curse is, just as you might expect, that the Fortran 90 programmer can't control the interprocessor communication, even when it is desirable to do so. A few regular communication patterns are "known" to the compiler through Fortran 90 intrinsic functions, for example `b=transpose(a)`. These, presumably, are done in an optimal way. However, many other regular patterns of communication, which might also allow highly optimized implementations, don't have corresponding intrinsic functions. (An obvious example is the "butterfly" pattern of communication that occurs in fast Fourier transforms.) These, if coded in Fortran 90 by using general vector subscripts (e.g., `barr=arr(iarr)` or `barr(jarr)=arr`, where `iarr` and `jarr` are integer arrays), lose all possibility of being optimized. The compiler can't distinguish a communication step with regular structure from one with general structure, so it must assume the worst case, potentially resulting in very slow execution.

About the only thing a Fortran 90 programmer can do is to start with a general awareness of the kind of apparently parallel constructions that *might* be quite slow on his/her parallel machine, and then to refine that awareness by actual experience and experiment. Here is our list of constructions most likely to cause interprocessor communication bottlenecks:

- vector subscripts, like `barr=arr(iarr)` or `barr(jarr)=arr` (that is, general gather/scatter operations)
- the `pack` and `unpack` intrinsic functions
- mixing positive strides and negative strides in a single expression (as in the above `b(1:10,1:10)+c(10:1:-1,10:1:-1)`)
- the `reshape` intrinsic when used with the `order` argument
- possibly, the `cshift` and `eoshift` extrinsics, especially for nonsmall values of the shift.

On the other hand, the fact is that these constructions *are* parallel, and *are* there for you to use. If the alternative to using them is strictly serial code, you should almost always give them a try.

Linear Algebra

You should be alert for opportunities to use combinations of the `matmul`, `spread`, and `dot_product` intrinsics to perform complicated linear algebra calculations. One useful intrinsic that is not provided in Fortran 90 is the *outer product*

of two vectors,

$$c_{ij} = a_i b_j \quad (22.1.5)$$

We already know how to implement this (cf. equation 22.1.3):

```
c = spread(a,dim=2,ncopies=size(b))*spread(b,dim=1,ncopies=size(a))
```

In fact, this operation occurs frequently enough to justify making it a utility function, `outerprod`, which we will do in Chapter 23. There we also define other “outer” operations between vectors, where the multiplication in the outer product is replaced by another binary operation, such as addition or division.

Here is an example of using these various functions: Many linear algebra routines require that a submatrix be updated according to a formula like

$$a_{jk} = a_{jk} + b_i a_{ji} \sum_{p=i}^m a_{pi} a_{pk}, \quad j = i, \dots, m, \quad k = l, \dots, n \quad (22.1.6)$$

where i, m, l , and n are fixed values. Using an array slice like `a(:,i)` to turn a_{pi} into a vector indexed by p , we can code the sum with a `matmul`, yielding a vector indexed by k :

```
temp(1:n)=b(i)*matmul(a(i:m,i),a(i:m,1:n))
```

Here we have also included the multiplication by b_i , a scalar for fixed i . The vector `temp`, along with the vector $a_{ji} = a(:,i)$, is then turned into a matrix by the `outerprod` utility and used to increment a_{jk} :

```
a(i:m,1:n)=a(i:m,1:n)+outerprod(a(i:m,i),temp(1:n))
```

Sometimes the update formula is similar to (22.1.6), but with a slight permutation of the indices. Such cases can be coded as above if you are careful about the order of the quantities in the `matmul` and the `outerprod`.

22.2 Linear Recurrence and Related Calculations

We have already seen that Fortran 90's *array constructor with implied do list* can be used to generate simple series of integers, like `(/ (i,i=1,n) /)`. Slightly more generally, one might want to generate an arithmetic progression, by the formula

$$v_j = b + (j - 1)a, \quad j = 1, \dots, n \quad (22.2.1)$$

This is readily coded as

```
v(1:n) = (/ (b+(j-1)*a, j=1,n) /)
```

Although it is concise, and valid, *we don't like this coding*. The reason is that it violates the fundamental rule of "thinking parallel": it turns a parallel operation across a data vector into a serial do-loop over the components of that vector. Yes, we know that the compiler might be smart enough to generate parallel code for implied do lists; but it also might *not* be smart enough, here or in more complicated examples.

Equation (22.2.1) is also the simplest example of a *linear recurrence relation*. It can be rewritten as

$$v_1 = b, \quad v_j = v_{j-1} + a, \quad j = 2, \dots, n \quad (22.2.2)$$

In this form (assuming that, in more complicated cases, one doesn't know an explicit solution like equation 22.2.1) one can't write an explicit array constructor. Code like

```
v(1) = b
v(2:n) = (/ (v(j-1)+a, j=2,n) /)      ! wrong
```

is legal Fortran 90 syntax, but illegal semantics; it does *not* do the desired recurrence! (The rules of Fortran 90 require that all the components of `v` on the right-hand side be evaluated before any of the components on the left-hand side are set.) Yet, as we shall see, techniques for accomplishing the evaluation in parallel are available.

With this as our starting point, we now survey some particular tricks of the (parallel) trade.

Subvector Scaling: Arithmetic and Geometric Progressions

For explicit arithmetic progressions like equation (22.2.1), the simplest parallel technique is *subvector scaling* [1]. The idea is to work your way through the desired vector in larger and larger parallel chunks:

$$\begin{aligned}
 v_1 &= b \\
 v_2 &= b + a \\
 v_{3\dots4} &= v_{1\dots2} + 2a \\
 v_{5\dots8} &= v_{1\dots4} + 4a \\
 v_{9\dots16} &= v_{1\dots8} + 8a
 \end{aligned} \tag{22.2.3}$$

And so on, until you reach the length of your vector. (The last step will not necessarily go all the way to the next power of 2, therefore.) The powers of 2, times a , can of course be obtained by successive doublings, rather than the explicit multiplications shown above.

You can see that subvector scaling requires about $\log_2 n$ parallel steps to process a vector of length n . Equally important for serial machines, or SSP machines, the scalar operation count for subvector scaling is no worse than entirely serial code: each new component v_i is produced by a single addition.

If addition is replaced by multiplication, the identical algorithm will produce geometric progressions, instead of arithmetic progressions. In Chapter 23, we will use subvector scaling to implement our utility functions `arth` and `geop` for these two progressions. (You can then call one of these functions instead of recoding equation 22.2.3 every time you need it.)

Vector Reduction: Evaluation of Polynomials

Logically related to subvector scaling is the case where a calculation can be parallelized across a vector that *shrinks* by a factor of 2 in each iteration, until a desired *scalar* result is reached. A good example of this is the parallel evaluation of a polynomial [2]

$$P(x) = \sum_{j=0}^N c_j x^j \tag{22.2.4}$$

For clarity we take the special case of $N = 5$. Start with the vector of coefficients (imagining appended zeros, as shown):

$$c_0, \quad c_1, \quad c_2, \quad c_3, \quad c_4, \quad c_5, \quad 0, \quad \dots$$

Now, add the elements by pairs, multiplying the second of each pair by x :

$$c_0 + c_1x, \quad c_2 + c_3x, \quad c_4 + c_5x, \quad 0, \quad \dots$$

Now, the same operation, but with the multiplier x^2 :

$$(c_0 + c_1x) + (c_2 + c_3x)x^2, \quad (c_4 + c_5x) + (0)x^2, \quad 0, \quad \dots$$

And a final time, with multiplier x^4 :

$$[(c_0 + c_1x) + (c_2 + c_3x)x^2] + [(c_4 + c_5x) + (0)x^2]x^4, \quad 0, \quad \dots$$

We are left with a vector of (active) length 1, whose value is the desired polynomial evaluation. (You can see that the zeros are just a bookkeeping device for taking account of the case where the active subvector has odd length.) The key point is that the combining by pairs is a parallel operation at each stage.

As in subvector scaling, there are about $\log_2 n$ parallel stages. Also as in subvector scaling, our total operations count is only negligibly different from purely scalar code: We do one add and one multiply for each original coefficient c_j . The only extra operations are $\log_2 n$ successive squarings of x ; but this comes with the extra benefit of better roundoff properties than the standard scalar coding. In Chapter 23 we use vector reduction to implement our utility function `poly` for polynomial evaluation.

Recursive Doubling: Linear Recurrence Relations

Please don't confuse our use of the word "recurrence" (as in "recurrence relation," "linear recurrence," or equation 22.2.2) with the words "recursion" and "recursive," which both refer to the idea of a subroutine calling itself to obtain an efficient or concise algorithm. There are ample grounds for confusion, because recursive algorithms are in fact a good way of obtaining parallel solutions to linear recurrence relations, as we shall now see!

Consider the general first order linear recurrence relation

$$u_j = a_j + b_{j-1}u_{j-1}, \quad j = 2, 3, \dots, n \quad (22.2.5)$$

with initial value $u_1 = a_1$. On a serial machine, we evaluate such a recurrence with a simple do-loop. To parallelize the recurrence, we can employ the powerful general strategy of *recursive doubling*. Write down equation (22.2.5) for $2j$ and for $2j - 1$:

$$u_{2j} = a_{2j} + b_{2j-1}u_{2j-1} \quad (22.2.6)$$

$$u_{2j-1} = a_{2j-1} + b_{2j-2}u_{2j-2} \quad (22.2.7)$$

Substitute equation (22.2.7) in equation (22.2.6) to eliminate u_{2j-1} and get

$$u_{2j} = (a_{2j} + a_{2j-1}b_{2j-1}) + (b_{2j-2}b_{2j-1})u_{2j-2} \quad (22.2.8)$$

This is a new recurrence of the same form as (22.2.5) but over only the even u_j , and hence involving only $n/2$ terms. Clearly we can continue this process recursively, halving the number of terms in the recurrence at each stage, until we are left with a recurrence of length 1 or 2 that we can do explicitly. Each time we finish a subpart of the recursion, we fill in the odd terms in the recurrence, using equation (22.2.7). In practice, it's even easier than it sounds. Turn to Chapter B5 to see a straightforward implementation of this algorithm as the recipe `recur1`.

On a machine with more processors than n , all the arithmetic at each stage of the recursion can be done simultaneously. Since there are of order $\log n$ stages in the

recursion, the execution time is $O(\log n)$. The total number of operations carried out is of order $n + n/2 + n/4 + \dots = O(n)$, the same as for the obvious serial do-loop.

In the utility routines of Chapter 23, we will use recursive doubling to implement the routines `poly_term`, `cumsum`, and `cumprod`. We *could* use recursive doubling to implement parallel versions of `arth` and `geop` (arithmetic and geometric progressions), and `zroots_unity` (complex n th roots of unity), but these can be done slightly more efficiently by subvector scaling, as discussed above.

Cyclic Reduction: Linear Recurrence Relations

There is a variant of recursive doubling, called *cyclic reduction*, that can be implemented with a straightforward iteration loop, instead of a recursive procedure call. [3] Here we start by writing down the recurrence (22.2.5) for *all* adjacent terms u_j and u_{j-1} (not just the even ones, as before). Eliminating u_{j-1} , just as in equation (22.2.8), gives

$$u_j = (a_j + a_{j-1}b_{j-1}) + (b_{j-2}b_{j-1})u_{j-2} \quad (22.2.9)$$

which is a first order recurrence with new coefficients a'_j and b'_j . Repeating this process gives successive formulas for u_j in terms of u_{j-2} , u_{j-4} , u_{j-8} , ... The procedure terminates when we reach u_{j-n} (for n a power of 2), which is zero for all j . Thus the last step gives u_j equal to the last set of a'_j 's.

Here is a code fragment that implements cyclic reduction by direct iteration. The quantities a'_j are stored in the variable `recur1`.

```
recur1=a
bb=b
j=1
do
  if (j >= n) exit
  recur1(j+1:n)=recur1(j+1:n)+bb(j:n-1)*recur1(1:n-j)
  bb(2*j:n-1)=bb(2*j:n-1)*bb(j:n-j-1)
  j=2*j
enddo
```

In cyclic reduction the length of the vector u_j that is updated at each stage does *not* decrease by a factor of 2 at each stage, but rather only decreases from $\sim n$ to $\sim n/2$ during all $\log_2 n$ stages. Thus the total number of operations carried out is $O(n \log n)$, as opposed to $O(n)$ for recursive doubling. For a serial machine or SSP machine, therefore, cyclic reduction is rarely superior to recursive doubling when the latter can be used. For an MMP machine, however, the issue is less clear cut, because the pattern of communication in cyclic reduction is quite different (and, for some parallel architectures, possibly more favorable) than that of recursive doubling.

Second Order Recurrence Relations

Consider the second order recurrence relation

$$y_j = a_j + b_{j-2}y_{j-1} + c_{j-2}y_{j-2}, \quad j = 3, 4, \dots, n \quad (22.2.10)$$

with initial values

$$y_1 = a_1, \quad y_2 = a_2 \quad (22.2.11)$$

Our labeling of subscripts is designed to make it easy to enter the coefficients in a computer program: You need to supply $a_1, \dots, a_n, b_1, \dots, b_{n-2}$, and c_1, \dots, c_{n-2} . Rewrite the recurrence relation in the form ([3])

$$\begin{pmatrix} y_j \\ y_{j+1} \end{pmatrix} = \begin{pmatrix} 0 \\ a_{j+1} \end{pmatrix} + \begin{pmatrix} 0 & 1 \\ c_{j-1} & b_{j-1} \end{pmatrix} \begin{pmatrix} y_{j-1} \\ y_j \end{pmatrix}, \quad j = 2, \dots, n-1 \quad (22.2.12)$$

that is,

$$\mathbf{u}_j = \mathbf{a}_j + \mathbf{b}_{j-1} \cdot \mathbf{u}_{j-1}, \quad j = 2, \dots, n-1 \quad (22.2.13)$$

where

$$\mathbf{u}_j = \begin{pmatrix} y_j \\ y_{j+1} \end{pmatrix}, \quad \mathbf{a}_j = \begin{pmatrix} 0 \\ a_{j+1} \end{pmatrix}, \quad \mathbf{b}_{j-1} = \begin{pmatrix} 0 & 1 \\ c_{j-1} & b_{j-1} \end{pmatrix}, \quad j = 2, \dots, n-1 \quad (22.2.14)$$

and

$$\mathbf{u}_1 = \mathbf{a}_1 = \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} = \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \quad (22.2.15)$$

This is a first order recurrence relation for the vectors \mathbf{u}_j , and can be solved by the algorithm described above (and implemented in the recipe `recur1`). The only difference is that the multiplications are matrix multiplications with the 2×2 matrices \mathbf{b}_j . After the first recursive call, the zeros in \mathbf{a} and \mathbf{b} are lost, so we have to write the routine for general two-dimensional vectors and matrices.

Note that this algorithm does not avoid the potential instability problems associated with second order recurrences that are discussed in §5.5 of Volume 1. Also note that the algorithm generalizes in the obvious way to higher-order recurrences: An n th order recurrence can be written as a first order recurrence involving n -dimensional vectors and matrices.

Parallel Solution of Tridiagonal Systems

Closely related to recurrence relations, recursive doubling, and cyclic reduction is the parallel solution of tridiagonal systems. Since Fortran 90 vectors “know their own size,” it is most logical to number the components of both the sub- and super-diagonals of the tridiagonal matrix from 1 to $N-1$. Thus equation (2.4.1), here written in the special case of $N=7$, becomes (blank elements denoting zero),

$$\begin{bmatrix} b_1 & c_1 & & & & & \\ a_1 & b_2 & c_2 & & & & \\ & a_2 & b_3 & c_3 & & & \\ & & a_3 & b_4 & c_4 & & \\ & & & a_4 & b_5 & c_5 & \\ & & & & a_5 & b_6 & c_6 \\ & & & & & a_6 & b_7 \end{bmatrix} \cdot \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \\ u_5 \\ u_6 \\ u_7 \end{bmatrix} = \begin{bmatrix} r_1 \\ r_2 \\ r_3 \\ r_4 \\ r_5 \\ r_6 \\ r_7 \end{bmatrix} \quad (22.2.16)$$

The basic idea for solving equation (22.2.16) on a parallel computer is to partition the problem into even and odd elements, recurse to solve the former, and

then solve the latter in parallel. Specifically, we first rewrite (22.2.16), by permuting its rows and columns, as

$$\begin{bmatrix} b_1 & & & c_1 & & \\ & b_3 & & a_2 & c_3 & \\ & & b_5 & & a_4 & c_5 \\ & & & b_7 & & a_6 \\ a_1 & c_2 & & & b_2 & \\ & a_3 & c_4 & & & b_4 \\ & & a_5 & c_6 & & b_6 \end{bmatrix} \cdot \begin{bmatrix} u_1 \\ u_3 \\ u_5 \\ u_7 \\ u_2 \\ u_4 \\ u_6 \end{bmatrix} = \begin{bmatrix} r_1 \\ r_3 \\ r_5 \\ r_7 \\ r_2 \\ r_4 \\ r_6 \end{bmatrix} \quad (22.2.17)$$

Now observe that, by row operations that subtract multiples of the first four rows from each of the last three rows, we can eliminate all nonzero elements in the lower-left quadrant. The price we pay is bringing some new elements into the lower-right quadrant, whose nonzero elements we now call x 's, y 's, and z 's. We call the modified right-hand sides q . The transformed problem is now

$$\begin{bmatrix} b_1 & & & c_1 & & \\ & b_3 & & a_2 & c_3 & \\ & & b_5 & & a_4 & c_5 \\ & & & b_7 & & a_6 \\ & & & & y_1 & z_1 \\ & & & & x_1 & y_2 & z_2 \\ & & & & & x_2 & y_3 \end{bmatrix} \cdot \begin{bmatrix} u_1 \\ u_3 \\ u_5 \\ u_7 \\ u_2 \\ u_4 \\ u_6 \end{bmatrix} = \begin{bmatrix} r_1 \\ r_3 \\ r_5 \\ r_7 \\ q_1 \\ q_2 \\ q_3 \end{bmatrix} \quad (22.2.18)$$

Notice that the last three rows form a new, smaller, tridiagonal problem, which we can solve simply by recursing! Once its solution is known, the first four rows can be solved by a simple, parallelizable, substitution. This algorithm is implemented in `tridag` in Chapter B2.

The above method is essentially cyclic reduction, but in the case of the tridiagonal problem, it does not “unwind” into a simple iteration; on the contrary, a recursive subroutine is required. For discussion of this and related methods for parallelizing tridiagonal systems, and references to the literature, see Hockney and Jesshope [3].

Recursive doubling can also be used to solve tridiagonal systems, the method requiring the parallel solution (as above) of both a first order recurrence and a second order recurrence [3,4]. For tridiagonal systems, however, cyclic reduction is usually more efficient than recursive doubling.

22.3 Parallel Synthetic Division and Related Algorithms

There are several techniques for parallelization that relate to synthetic division but that can also find application in wider contexts, as we shall see.

Cumulants of a Polynomial

Suppose we have a polynomial

$$P(x) = \sum_{j=0}^N c_j x^{N-j} \quad (22.3.1)$$

(Note that, here, the c_j 's are indexed from highest degree to lowest, the reverse of the usual convention.) Then we can define the *cumulants* of the polynomial to be partial sums that occur in the polynomial's usual, serial evaluation,

$$\begin{aligned} P_0 &= c_0 \\ P_1 &= c_0 x + c_1 \\ &\dots \\ P_N &= c_0 x^N + \dots + c_N = P(x) \end{aligned} \quad (22.3.2)$$

Evidently, the cumulants satisfy a simple, linear first order recurrence relation,

$$P_0 = c_0, \quad P_j = c_j + xP_{j-1}, \quad j = 2, \dots, N \quad (22.3.3)$$

This is slightly simpler than the general first order recurrence, because the value of x does not depend on j . We already know, from §22.2's discussion of recursive doubling, how to parallelize equation (22.3.3) via a recursive subroutine. In Chapter 23, the utility routine `poly_term` will implement just such a procedure. An example of a routine that calls `poly_term` to evaluate a recurrence equivalent to equation (22.3.3) is `eulsum` in Chapter B5.

Notice that while we could use equation (22.3.3), parallelized by recursive doubling, simply to evaluate the polynomial $P(x) = P_N$, this is likely somewhat slower than the alternative technique of vector reduction, also discussed in §22.2, and implemented in the utility function `poly`. Equation (22.3.3) should be saved for cases where the rest of the P_j 's (not just P_N) can be put to good use.

Synthetic Division by a Monomial

We now show that evaluation of the cumulants of a polynomial is equivalent to synthetic division of the polynomial by a monomial, also called *deflation* (see §9.5 in Volume 1). To review briefly, and by example, here is a standard tableau from high school algebra for the (long) division of a polynomial $2x^3 - 7x^2 + x + 3$ by the monomial factor $x - 3$.

$$\begin{array}{r}
 2x^2 - x - 2 \\
 x - 3 \overline{) 2x^3 - 7x^2 + x + 3} \\
 \underline{2x^3 - 6x^2} \\
 -x^2 + x \\
 \underline{-x^2 + 3x} \\
 -2x + 3 \\
 \underline{-2x + 6} \\
 -3 \text{ (remainder)}
 \end{array} \tag{22.3.4}$$

Now, here is the same calculation written as a *synthetic division*, really the same procedure as tableau (22.3.4), but with unnecessary notational baggage omitted (and also a changed sign for the monomial's constant, so that subtractions become additions):

$$\begin{array}{r}
 6 \quad -3 \quad -6 \\
 3 \overline{) 2 \quad -7 \quad +1 \quad +3} \\
 \underline{2 \quad -1 \quad -2 \quad -3}
 \end{array} \tag{22.3.5}$$

If we substitute symbols for the above quantities with the correspondence

$$\begin{array}{r}
 x \overline{) c_0 \quad c_1 \quad c_2 \quad c_3} \\
 P_0 \quad P_1 \quad P_2 \quad P_3
 \end{array} \tag{22.3.6}$$

then it is immediately clear that the P_j 's in equation (22.3.6) are simply the P_j 's of equation (22.3.3); the calculation is thus parallelizable by recursive doubling. In this context, the utility routine `poly_term` is used by the routine `zroots` in Chapter B9.

Repeated Synthetic Division

It is well known from high-school algebra that repeated synthetic division of a polynomial yields, as the remainders that occur, first the value of the polynomial, next the value of its first derivative, and then (up to multiplication by the factorial of an integer) the values of higher derivatives.

If you want to parallelize the calculation of the value of a polynomial and one or two of its derivatives, it is not unreasonable to evaluate equation (22.3.3), parallelized by recursive doubling, two or three times. Our routine `ddpoly` in Chapter B5 is meant for such use, and it does just this, as does the routine `laguer` in Chapter B9.

There are other cases, however, for which you want to perform repeated synthetic division and “go all the way,” until only a constant remains. For example, this is the preferred way of “shifting a polynomial,” that is, evaluating the coefficients of a polynomial in a variable y that differs from the original variable x by an additive constant. (The recipe `pcshft` has this as its assigned task.) By way of example, consider the polynomial $3x^3 + x^2 + 4x + 7$, and let us perform repeated synthetic division by a general monomial $x - a$. The conventional calculation then proceeds according to the following tableau, reading it in conventional lexical order (left-to-right and top-to-bottom):

$$\begin{array}{ccccccc}
 3 & & 1 & & 4 & & 7 \\
 \downarrow & & \downarrow & & \downarrow & & \downarrow \\
 3 & \xrightarrow{a} & 3a+1 & \xrightarrow{a} & 3a^2+a+4 & \xrightarrow{a} & 3a^3+a^2+4a+7 \\
 \downarrow & & \downarrow & & \downarrow & & \\
 3 & \xrightarrow{a} & 6a+1 & \xrightarrow{a} & 9a^2+2a+4 & & \\
 \downarrow & & \downarrow & & & & \\
 3 & \xrightarrow{a} & 9a+1 & & & & \\
 \downarrow & & & & & & \\
 3 & & & & & &
 \end{array} \tag{22.3.7}$$

Here, each row (after the first) shows a synthetic division or, equivalently, evaluation of the cumulants of the polynomial whose coefficients are the preceding row. The results at the right edge of the rows are the values of the polynomial and (up to integer factorials) its three nonzero derivatives, or (equivalently, without factorials) coefficients of the shifted polynomial.

We could parallelize the calculation of each row of tableau (22.3.7) by recursive doubling. That is a lot of recursion, which incurs a nonnegligible overhead. A much better way of doing the calculation is to deform tableau (22.3.7) into the following equivalent tableau,

$$\begin{array}{ccccccc}
 3 \longrightarrow & & 3 & & & & \\
 & & a \downarrow & \searrow & & & \\
 1 \longrightarrow & & 3a+1 & & 3 & & \\
 & & a \downarrow & \searrow & a \downarrow & \searrow & \\
 4 \longrightarrow & & 3a^2+a+4 & & 6a+1 & & 3 \\
 & & a \downarrow & \searrow & a \downarrow & \searrow & a \downarrow \searrow \\
 7 \longrightarrow & 3a^3+a^2+4a+7 & & 9a^2+2a+4 & & 9a+1 & 3
 \end{array} \tag{22.3.8}$$

Now each row explicitly depends on only the previous row (and the given first column), so the rows can be calculated in turn by an explicit parallel expression, with no recursive calls needed. An example of coding (22.3.8) in Fortran 90 can be found in the routine `pcshft` in Chapter B5. (It is also possible to eliminate most of the multiplications in (22.3.8), at the expense of a much smaller number of divisions. We have not done this because of the necessity for then treating all possible divisions by zero as special cases. See [1] for details and references.)

Actually, the deformation of (22.3.7) into (22.3.8) is the same trick as was used in Volume 1, p. 167, for evaluating a polynomial and its derivative simultaneously, also generalized in the Fortran 77 implementation of the routine `ddpoly` (Chapter 5). In the Fortran 90 implementation of `ddpoly` (Chapter B5) we *don't* use this trick, but instead use `poly_term`, because, there, we want to parallelize over the length of the polynomial, not over the number of desired derivatives.

Don't confuse the cases of *iterated* synthetic division, discussed here, with the simpler case of doing many simultaneous synthetic divisions. In the latter case, you can simply implement equation (22.3.3) serially, exactly as written, but with each operation being data-parallel across your problem set. (This case occurs in our routine `polcoe` in Chapter B3.)

Polynomial Coefficients from Roots

A parallel calculation algorithmically very similar to (22.3.7) or (22.3.8) occurs when we want to find the coefficients of a polynomial $P(x)$ from its roots r_1, \dots, r_N . For this, the tableau is

$$\begin{array}{rcccl}
 & r_1 & & & \\
 r_2 : & \downarrow & \searrow & & \\
 & r_1 + r_2 & r_1 r_2 & & \\
 r_3 : & \downarrow & \searrow & \downarrow & \searrow \\
 & r_1 + r_2 + r_3 & r_1 r_2 + r_3(r_1 + r_2) & r_1 r_2 r_3 &
 \end{array} \quad (22.3.9)$$

As before, the rows are computed consecutively, from top to bottom. Each row is computed via a single parallel expression. Note that values moving on vertical arrows are simply added in, while values moving on diagonal arrows are multiplied by a new root before adding. Examples of coding (22.3.9) in Fortran 90 can be found in the routines `vander` (Chapter B2) and `polcoe` (Chapter B3).

An equivalent deformation of (22.3.9) is

$$\begin{array}{rcccl}
 & r_1 & & & \\
 r_2 : & \downarrow & \searrow & & \\
 & r_1 r_2 & r_1 + r_2 & & \\
 r_3 : & \downarrow & \searrow & \downarrow & \searrow \\
 & r_1 r_2 r_3 & r_1 r_2 + r_3(r_1 + r_2) & r_1 + r_2 + r_3 &
 \end{array} \quad (22.3.10)$$

Here the diagonal arrows are simple additions, while the vertical arrows represent multiplication by a root value. Note that the coefficient answers in (22.3.10) come out in the opposite order from (22.3.9). An example of coding (22.3.10) in Fortran 90 can be found in the routine `fixrts` in Chapter B13.

22.4 Fast Fourier Transforms

Fast Fourier transforms are beloved by computer scientists, especially those who are interested in parallel algorithms, because the FFT's hierarchical structure generates a complicated, but analyzable, set of requirements for interprocessor communication on MMPs. Thus, almost all books on parallel algorithms (e.g., [1–3]) have a chapter on FFTs.

Unfortunately, the resulting algorithms are highly specific to particular parallel architectures, and therefore of little use to us in writing general purpose code in an architecture-independent parallel language like Fortran 90.

Luckily there is a good alternative that covers almost all cases of both serial and parallel machines. If, for a one-dimensional FFT of size N , one is satisfied with parallelism of order \sqrt{N} , then there is a good, general way of achieving a parallel FFT with *quite minimal* interprocessor communication; and the communication required is simply the matrix transpose operation, which Fortran 90 implements as an intrinsic. That is the approach that we discuss in this section, and implement in Chapter B12.

For a machine with M processors, this approach will saturate the processors (the desirable condition where none are idle) when the size of a one-dimensional Fourier transform, N , is large enough: $N > M^2$. Smaller N 's will not achieve maximum parallelism. But such N 's are in fact so small for one-dimensional problems that they are unlikely to be the rate-determining step in scientific calculations. If they are, it is usually because you are doing many such transforms independently, and you should recover “outer parallelism” by doing them all at once.

For two or more dimensions, the adopted approach will saturate M processors when *each* dimension of the problem is larger than M .

Column- and Row-Parallel FFTs

The basic building block that we assume (and implement in Chapter B12) is a routine for simultaneously taking the FFT of each *row* of a two-dimensional matrix. The method is exactly that of Volume 1's `four1` routine, but with array sections like `data(:,j)` replacing scalars like `data(j)`. Chapter B12's implementation of this is a routine called `fourrow`. If all the data for one column (that is, all the values `data(i,:)`, for some i) are local to a single processor, then the parallelism involves no interprocessor communication at all: The independent FFTs simply proceed, data parallel and in lockstep. This is architecture-independent parallelism with a vengeance.

We will also need to take the FFT of each *column* of a two-dimensional matrix. One way to do this is to take the transpose (a Fortran 90 intrinsic that hides a lot of interprocessor communication), then take the FFT of the rows using `fourrow`, then take the transpose again. An alternative method is to recode the `four1` routine with array sections in the other dimension (`data(j,:)` replacing `four1`'s scalars (`data(j)`). This scheme, in Chapter B12, is a routine called `fourcol`. In this case, good parallelism will be achieved only if the values `data(:,i)`, for some i , are local to a single processor. Of course, Fortran 90 does not give the user direct control over how data are distributed over the machine; but extensions such as HPF are designed to give just such control.

On a serial machine, you might think that `fourrow` and `fourcol` should have identical timings (acting on a square matrix, say). The two routines do exactly the same operations, after all. Not so! On modern serial computers, `fourrow` and `fourcol` can have timings that differ by a factor of 2 or more, even when their detailed arithmetic is made identical (by giving to one a data array that is the transpose of the data array given to the other). This effect is due to the multilevel cache architecture of most computer memories, and the fact that serial Fortran always stores matrices by columns (first index changing most rapidly). On our workstations, `fourrow` is significantly faster than `fourcol`, and this is likely the generic behavior. However, we do not exclude the possibility that some machines, and some sizes of matrices, are the other way around.

One-Dimensional FFTs

Turn now to the problem of how to do a single, one-dimensional, FFT. We are given a complex array f of length N , an integer power of 2. The basic idea is to address the input array as if it were a two-dimensional array of size $m \times M$, where m and M are each integer powers of 2. Then the components of f can be addressed as

$$f(Jm + j), \quad 0 \leq j < m, \quad 0 \leq J < M \quad (22.4.1)$$

where the j index changes more rapidly, the J index more slowly, and parentheses denote Fortran-style subscripts.

Now, suppose we had some magical (parallel) method to compute the discrete Fourier transform

$$F(kM + K) \equiv \sum_{j,J} e^{2\pi i(kM+K)(Jm+j)/(Mm)} f(Jm + j), \quad 0 \leq k < m, \quad 0 \leq K < M \quad (22.4.2)$$

Then, you can see that the indices k and K would address the desired result (FFT of the original array), with K varying more rapidly.

Starting with equation (22.4.2) it is easy to verify the following identity,

$$F(kM + K) = \sum_j \left[e^{2\pi i j k / m} \left(e^{2\pi i j K / (Mm)} \left[\sum_J e^{2\pi i j K / M} f(Jm + j) \right] \right) \right] \quad (22.4.3)$$

But this, reading it from the innermost operation outward, is just the magical method that we need:

- Reshape the original array to $m \times M$ in Fortran normal order (storage by columns).
- FFT on the second (column) index for all values of the first (row) index, using the routine `fourrow`.
- Multiply each component by a phase factor $\exp[2\pi i j K / (Mm)]$.
- Transpose.

- Again FFT on the second (column) index for all values of the first (row) index, using the routine `fourrow`.
- Reshape the two-dimensional array back into one-dimensional output.

The above scheme uses `fourrow` exclusively, on the assumption that it is faster than its sibling `fourcol`. When that is the case (as we typically find), it is likely that the above method, implemented as `four1` in Chapter B12, is faster, even on scalar machines, than Volume 1's scalar version of `four1` (Chapter 12). The reason, as already mentioned, is that `fourrow`'s parallelism is taking better advantage of cache memory locality.

If `fourrow` is *not* faster than `fourcol` on your machine, then you should instead try the following alternative scheme, using `fourcol` only:

- Reshape the original array to $m \times M$ in Fortran normal order (storage by columns).
- Transpose.
- FFT on the first (row) index for all values of the second (column) index, using the routine `fourcol`.
- Multiply each component by a phase factor $\exp[2\pi i j K / (Mm)]$.
- Transpose.
- Again FFT on the first (row) index for all values of the second (column) index, using the routine `fourcol`.
- Transpose.
- Reshape the two-dimensional array back into one-dimensional output.

In Chapter B12, this scheme is implemented as `four1_alt`. You might wonder why `four1_alt` has three transpose operations, while `four1` had only one. Shouldn't there be a symmetry here? No. Fortran makes the arbitrary, but consistent, choice of storing two-dimensional arrays by columns, and this choice favors `four1` in terms of transposes. Luckily, at least on our serial workstations, `fourrow` (used by `four1`) is faster than `fourcol` (used by `four1_alt`), so it is a double win.

For further discussion and references on the ideas behind `four1` and `four1_alt` see [4], where these algorithms are called the four-step and six-step frameworks, respectively.

22.5 Missing Language Features

A few facilities that are fairly important to parallel programming are missing from the Fortran 90 language standard. On scalar machines this lack is not a

problem, since one can readily program the missing features by using do-loops. On parallel machines, both SSP machines and MMP machines, one must hope that hardware manufacturers provide library routines, callable from Fortran 90, that provide access to the necessary facilities, or use extensions of Fortran 90, such as High Performance Fortran (HPF).

Scatter-with-Combine Functions

Fortran 90 allows the use of *vector subscripts* for so-called *gather* and *scatter* operations. For example, with the setup

```
REAL(SP), DIMENSION(6) :: arr,barr,carr
INTEGER(I4B), DIMENSION(6) :: iarr,jarr
...
iarr = (/ 1,3,5,2,4,6 /)
jarr = (/ 3,2,3,2,1,1 /)
```

Fortran 90 allows both the *one-to-one* gather and the *one-to-many* gather,

```
barr=arr(iarr)
carr=arr(jarr)
```

It also allows the one-to-one scatter,

```
barr(iarr)=carr
```

where the elements of *carr* are “scattered” into *barr* under the direction of the vector subscript *iarr*.

Fortran 90 does *not* allow the *many-to-one* scatter

```
barr(jarr)=carr      ! illegal for this jarr
```

because the repeated values in *jarr* try to assign different components of *carr* to the same location in *barr*. The result would not be deterministic.

Sometimes, however, one would in fact like a many-to-one construction, where the colliding elements get combined by a (commutative and associative) operation, like + or *, or *max()*. These so-called *scatter-with-combine* functions are readily implemented on serial machines by a do-loop, for example,

```
barr=0.
do j=1,size(carr)
  barr(jarr(j))=barr(jarr(j))+carr(j)
end do
```

Fortran 90 unfortunately provides no means for effecting scatter-with-combine functions in parallel. Luckily, almost all parallel machines do provide such a facility as a library program, as does HPF, where the above facility is called *SUM_SCATTER*. In Chapter 23 we will define utility routines *scatter_add* and *scatter_max* for scatter-with-combine functionalities, but the implementation given in Fortran 90 will be strictly serial, with a do-loop.

Skew Sections

Fortran 90 provides no good, parallel way to access the diagonal elements of a matrix, either to read them or to set them. Do-loops will obviously serve this need on serial machines. In principle, a construction like the following bizarre fragment could also be utilized,

```
REAL(SP), DIMENSION(n,n) :: mat
REAL(SP), DIMENSION(n*n) :: arr
REAL(SP), DIMENSION(n) :: diag
...
arr = reshape(mat,shape(arr))
diag = arr(1:n:n+1)
```

which extracts every $(n + 1)$ st element from a one-dimensional array derived by reshaping the input matrix. However, it is unlikely that any foreseeable parallel compiler will implement the above fragment without a prohibitive amount of unnecessary data movement; and code like the above is also exceedingly slow on all serial machines that we have tried.

In Chapter 23 we will define utility routines `get_diag`, `put_diag`, `diagadd`, `diagmult`, and `unit_matrix` to manipulate diagonal elements, but the implementation given in Fortran 90 will again be strictly serial, with do-loops.

Fortran 95 (see §21.6) will essentially fix Fortran 90's skew sections deficiency. For example, using its `forall` construction, the diagonal elements of an array can be accessed by a statement like

```
forall (j=1:20) diag(j) = arr(j,j)
```

SIMD vs. MIMD

Recall that we use “SIMD” (single-instruction, multiple data) and “data parallel” as interchangeable terms, and that “MIMD” (multiple-instruction, multiple data) is a more general programming model. (See §22.1.)

You should not be too quick to jump to the conclusion that Fortran 90's data parallel or SIMD model is “bad,” and that MIMD features, absent in Fortran 90, are therefore “good.” On the contrary, Fortran 90's basic data-parallel paradigm has a lot going for it. As we discussed in §22.1, most scientific problems naturally have a “data dimension” across which the time ordering of the calculation is irrelevant. Parallelism across this dimension, which is by nature most often SIMD, frees the mind to think clearly about the computational steps in an algorithm that actually need to be sequential. SIMD code has advantages of clarity and predictability that should not be taken lightly. The general MIMD model of “lots of different things all going on at the same time and communicating data with each other” is a programming and debugging nightmare.

Having said this, we must at the same time admit that a few MIMD features — most notably the ability to go through different logical branches for calculating different data elements in a data-parallel computation — are badly needed in certain programming situations. Fortran 90 is quite weak in this area.

Note that the `where...elsewhere...end where` construction is *not* a MIMD construction. Fortran 90 requires that the `where` clause be executed completely before the `elsewhere` is started. (This allows the results of any calculations in the former

clause to be available for use in the latter.) So, this construction cannot be used to allow two logical branches to be calculated in parallel.

Special functions, where one would like to calculate function values for an array of input quantities, are a particularly compelling example of the need for some MIMD access. Indeed, you will find that Chapter B6 contains a number of intricate, and in a few cases truly bizarre, workarounds, using allowed combinations of `merge`, `where`, and `CONTAINS` (the latter, for separating different logical branches into formally different subprograms).

Fortran 95's `ELEMENTAL` and `PURE` constructions, and to some extent also `forall` (whose body will be able to include `PURE` function calls), will go a long way towards providing exactly the kind of MIMD constructions that are most needed. Once Fortran 95 becomes available and widespread, you can expect to see a new version of this volume, with a much-improved Chapter B6.

Conversely, the number of routines outside of Chapter B6 that can be significantly improved by the use of MIMD features is relatively small; this illustrates the underlying viability of the basic data-parallel SIMD model, even in a future language version with useful MIMD features.

Chapter 23. Numerical Recipes Utility Functions for Fortran 90

23.0 Introduction and Summary Listing

This chapter describes and summarizes the Numerical Recipes utility routines that are used throughout the rest of this volume. A complete implementation of these routines in Fortran 90 is listed in Appendix C1.

Why do we need utility routines? Aren't there already enough of them built into the language as Fortran 90 intrinsics? The answers lie in this volume's dual purpose: to implement the Numerical Recipes routines in Fortran 90 code that runs efficiently on fast serial machines, *and* to implement them, wherever possible, with efficient parallel code for multiprocessor machines that will become increasingly common in the future. We have found three kinds of situations where additional utility routines seem desirable:

1. Fortran 90 is a big language, with many high-level constructs — single statements that actually result in a lot of computing. We like this; it gives the language the potential for expressing algorithms very readably, getting them “out of the mud” of microscopic coding. In coding the 350+ Recipes for this volume, we kept a systematic watch for bits of microscopic coding that were repeated in many routines, and that seemed to be at a lower level of coding than that aspired to by good Fortran 90 style. Once these bits were identified, we pulled them out and substituted calls to new utility routines. These are the utilities that arguably ought to be new language intrinsics, equally useful for serial and parallel machines. (A prime example is `swap`.)

2. Fortran 90 contains many highly parallelizable language constructions. But, as we have seen in §22.5, it is also missing a few important constructions. Most parallel machines will provide these missing elements as machine-coded library subroutines. Some of our utility routines are provided simply as a standard interface to these common, but nonstandard, functionalities. Note that it is the nature of these routines that our specific implementation, in Appendix C1, will be serial, and therefore inefficient on parallel machines. If you have a parallel machine, you will need to recode these; this often involves no more than substituting a one-line library function call for the body of our implementation. Utilities in this category will likely become unnecessary over time, either as machine-dependent libraries converge to standard interfaces, or as the utilities get added to future Fortran versions. (Indeed,

some routines in this category will be unnecessary in Fortran 95, once it is available; see §23.7.)

3. Some tasks should just be done differently in serial, versus parallel, implementation. Linear recurrence relations are a good example (§22.2). These are trivially coded with a do-loop on serial machines, but require a fairly elaborate recursive construction for good parallelization. Rather than provide separate serial and parallel versions of the Numerical Recipes, we have chosen to pull out of the Recipes, and into utility routines, some identifiable tasks of this kind. These are cases where some recoding of our implementation in Appendix C1 might result in improved performance on your particular hardware. Unfortunately, it is not so simple as providing a single “serial implementation” and another single “parallel implementation,” because even the seemingly simple word “serial” hides, at the hardware level, a variety of different degrees of pipelining, wide instructions, and so on. Appendix C1 therefore provides only a single implementation, although with some adjustable parameters that you can customize (by experiment) to maximize performance on your hardware.

The above three cases are not really completely distinct, and it is therefore not possible to assign any single utility routine to exactly one situation. Instead, we organize the rest of this chapter as follows: first, an alphabetical list, with short summary, of all the new utility routines; next, a series of short sections, grouped by functionality, that contain the detailed descriptions of the routines.

Alphabetical Listing

The following list gives an abbreviated mnemonic for the type, rank, and/or shape of the returned values (as in §21.4), the routine’s calling sequence (optional arguments shown in *italics*), and a brief, often incomplete, description. The complete description of the routine is given in the later section shown in square brackets.

For each entry, the number shown in parentheses is the approximate number of distinct Recipes in this book that make use of that particular utility function, and is thus a rough guide to that utility’s importance. (There may be multiple invocations of the utility in each such Recipe.) Where this number is small or zero, it is usually because the utility routine is a member of a related family of routines whose total usage was deemed significant enough to include, and we did not want users to have to “guess” which family members were instantiated.

- call `array_copy(src,dest,n_copied,n_not_copied)`
 Copy one-dimensional array (whose size is not necessarily known).
 [23.1] (9)
- [Arr] `arrth(first,increment,n)`
 Return an arithmetic progression as an array. [23.4] (55)
- call `assert(n1,n2,...,string)`
 Exit with error message if any logical arguments are false. [23.3] (50)
- [Int] `assert_eq(n1,n2,...,string)`
 Exit with error message if all integer arguments are not equal; otherwise
 return common value. [23.3] (133)
- [argTS] `cumprod(arr,seed)`

- Cumulative products of one-dimensional array, with optional seed value. [23.4] (3)
- [argTS] `cumsum(arr, seed)`
Cumulative sums of one-dimensional array, with optional seed value. [23.4] (9)
- `call diagadd(mat, diag)`
Adds vector to diagonal of a matrix. [23.7] (4)
- `call diagsmult(mat, diag)`
Multiplies vector into diagonal of a matrix. [23.7] (2)
- [Arr] `geop(first, factor, n)`
Return a geometrical progression as an array. [23.4] (7)
- [Arr] `get_diag(mat)`
Gets diagonal of a matrix. [23.7] (2)
- [Int] `ifirstloc(arr)`
Location of first true value in a logical array, returned as an integer. [23.2] (3)
- [Int] `imaxloc(arr)`
Location of array maximum, returned as an integer. [23.2] (11)
- [Int] `iminloc(arr)`
Location of array minimum, returned as an integer. [23.2] (8)
- [Mat] `lower_triangle(j, k, extra)`
Returns a lower triangular logical mask. [23.7] (1)
- `call nrerror(string)`
Exit with error message. [23.3] (96)
- [Mat] `outerand(a, b)`
Returns the outer logical and of two vectors. [23.5] (1)
- [Mat] `outerdiff(a, b)`
Returns the outer difference of two vectors. [23.5] (4)
- [Mat] `outerdiv(a, b)`
Returns the outer quotient of two vectors. [23.5] (0)
- [Mat] `outerprod(a, b)`
Returns the outer product of two vectors. [23.5] (14)
- [Mat] `outersum(a, b)`
Returns the outer sum of two vectors. [23.5] (0)
- [argTS] `poly(x, coeffs, mask)`
Evaluate a polynomial $P(x)$ for one or more values x , with optional mask. [23.4] (15)
- [argTS] `poly_term(a, x)`
Returns partial cumulants of a polynomial, equivalent to synthetic

- division. [23.4] (4)
- call put_diag(diag,mat)
Sets diagonal of a matrix. [23.7] (0)
- [Ptr] reallocate(p,n,m,...)
Reallocate pointer to new size, preserving its contents. [23.1] (5)
- call scatter_add(dest,source,dest_index)
Scatter-adds source vector to specified components of destination vector. [23.6] (2)
- call scatter_max(dest,source,dest_index)
Scatter-max source vector to specified components of destination vector. [23.6] (0)
- call swap(a,b,mask)
Swap corresponding elements of a and b. [23.1] (24)
- call unit_matrix(mat)
Sets matrix to be a unit matrix. [23.7] (6)
- [Mat] upper_triangle(j,k,extra)
Returns an upper triangular logical mask. [23.7] (4)
- [Real] vabs(v)
Length of a vector in L_2 norm. [23.8] (6)
- [CArr] zroots_unity(n,nn)
Returns nn consecutive powers of the complex nth root of unity. [23.4] (4)

Comment on Relative Frequencies of Use

We find it interesting to compare our frequency of using the `nrutil` utility routines, with our most used language intrinsics (see §21.4). On this basis, the following routines are as useful to us as the *top 10* language intrinsics: `arith`, `assert`, `assert_eq`, `outerprod`, `poly`, and `swap`. We strongly recommend that the X3J3 standards committee, as well as individual compiler library implementors, consider the inclusion of new language intrinsics (or library routines) that subsume the capabilities of at least these routines. In the next tier of importance, we would put some further cumulative operations (`geop`, `cumsum`), some other “outer” operations on vectors (e.g., `outerdiff`), basic operations on the diagonals of matrices (`get_diag`, `put_diag`, `diag_add`), and some means of access to an array of unknown size (`array_copy`).

23.1 Routines That Move Data

To describe our utility routines, we introduce two items of Fortran 90 pseudocode: We use the symbol **T** to denote some type and rank declaration (including

scalar rank, i.e., zero); and when we append a colon to a type specification, as in `INTEGER(I4B) (:)`, for example, we denote an array of the given type.

The routines `swap`, `array_copy`, and `realloc` simply move data around in useful ways.

* * *

swap (swaps corresponding elements)

User interface (or, “USE nrutil”):

```
SUBROUTINE swap(a,b,mask)
  T, INTENT(INOUT) :: a,b
  LOGICAL(LGT), INTENT(IN), OPTIONAL :: mask
END SUBROUTINE swap
```

Applicable types and ranks:

T \equiv any type, any rank

Types and ranks implemented (overloaded) in nrutil:

```
T  $\equiv$  INTEGER(I4B), REAL(SP), REAL(SP) (:), REAL(DP),
      COMPLEX(SPC), COMPLEX(SPC) (:), COMPLEX(SPC) (:,:),
      COMPLEX(DPC), COMPLEX(DPC) (:), COMPLEX(DPC) (:,:)
```

Action:

Swaps the corresponding elements of `a` and `b`. If `mask` is present, performs the swap only where `mask` is true. (Following code is the unmasked case. For speed at run time, the masked case is implemented by overloading, not by testing for the optional argument.)

Reference implementation:

```
T :: dum
dum=a
a=b
b=dum
```

* * *

array_copy (copy one-dimensional array)

User interface (or, “USE nrutil”):

```
SUBROUTINE array_copy(src,dest,n_copied,n_not_copied)
  T, INTENT(IN) :: src
  T, INTENT(OUT) :: dest
  INTEGER(I4B), INTENT(OUT) :: n_copied, n_not_copied
END SUBROUTINE array_copy
```

Applicable types and ranks:

T \equiv any type, rank 1

Types and ranks implemented (overloaded) in nrutil:

```
T  $\equiv$  INTEGER(I4B) (:), REAL(SP) (:), REAL(DP) (:)
```

Action:

Copies to a destination array `dest` the one-dimensional array `src`, or as much of `src` as will fit in `dest`. Returns the number of components copied as `n_copied`, and the number of components not copied as `n_not_copied`.

The main use of this utility is where `src` is an expression that returns an array whose size is not known in advance, for example, the value returned by the `pack` intrinsic.

Reference implementation:

```
n_copied=min(size(src),size(dest))
n_not_copied=size(src)-n_copied
dest(1:n_copied)=src(1:n_copied)
```

* * *

reallocate (reallocate a pointer, preserving contents)

User interface (or, “USE nrutil”):

```
FUNCTION reallocate(p,n[,m,...])
T, POINTER :: p, reallocate
INTEGER(I4B), INTENT(IN) :: n[,m,...]
END FUNCTION reallocate
```

Applicable types and ranks:

T \equiv any type, rank 1 or greater

Types and ranks implemented (overloaded) in nrutil:

```
T  $\equiv$  INTEGER(I4B)(:), INTEGER(I4B)(:,:), REAL(SP)(:),
REAL(SP)(:,:), CHARACTER(1)(:)
```

Action:

Allocates storage for a new array with shape specified by the integer(s) *n*, *m*, ... (equal in number to the rank of pointer *p*). Then, copies the contents of *p*’s target (or as much as will fit) into the new storage. Then, deallocates *p* and returns a pointer to the new storage.

The typical use is *p*=*reallocate*(*p*,*n*[,*m*,...]), which has the effect of changing the allocated size of *p* while preserving the contents.

The reference implementation, below, shows only the case of rank 1.

Reference implementation:

```
INTEGER(I4B) :: nold,ierr
allocate(reallocate(n),stat=ierr)
if (ierr /= 0) call &
    nrerror('reallocate: problem in attempt to allocate memory')
if (.not. associated(p)) RETURN
nold=size(p)
reallocate(1:min(nold,n))=p(1:min(nold,n))
deallocate(p)
```

23.2 Routines Returning a Location

Fortran 90’s intrinsics *maxloc* and *minloc* return rank-one arrays. When, in the most frequent usage, their argument is a one-dimensional array, the answer comes back in the inconvenient form of an array containing a single component, which cannot be itself used in a subscript calculation. While there are workaround tricks (e.g., use of the *sum* intrinsic to convert the array to a scalar), it seems clearer to define routines *imaxloc* and *iminloc* that return integers directly.

The routine *ifirstloc* adds a related facility missing among the intrinsics: Return the first true location in a logical array.

* * *

imaxloc (location of array maximum as an integer)*User interface (or, “USE nrutil”):*

```

FUNCTION imaxloc(arr)
  T, INTENT(IN) :: arr
  INTEGER(I4B) :: imaxloc
END FUNCTION imaxloc

```

*Applicable types and ranks:***T** \equiv any integer or real type, rank 1*Types and ranks implemented (overloaded) in nrutil:***T** \equiv INTEGER(I4B)(:), REAL(SP)(:)*Action:*

For one-dimensional arrays, identical to the `maxloc` intrinsic, except returns its answer as an integer rather than as `maxloc`’s somewhat awkward rank-one array containing a single component.

Reference implementation:

```

INTEGER(I4B), DIMENSION(1) :: imax
imax=maxloc(arr(:))
imaxloc=imax(1)

```

★ ★ ★

iminloc (location of array minimum as an integer)*User interface (or, “USE nrutil”):*

```

FUNCTION iminloc(arr)
  T, INTENT(IN) :: arr
  INTEGER(I4B) :: iminloc
END FUNCTION iminloc

```

*Applicable types and ranks:***T** \equiv any integer or real type, rank 1*Types and ranks implemented (overloaded) in nrutil:***T** \equiv REAL(SP)(:)*Action:*

For one-dimensional arrays, identical to the `minloc` intrinsic, except returns its answer as an integer rather than as `minloc`’s somewhat awkward rank-one array containing a single component.

Reference implementation:

```

INTEGER(I4B), DIMENSION(1) :: imin
imin=minloc(arr(:))
iminloc=imin(1)

```

★ ★ ★

ifirstloc (returns location of first “true” in a logical vector)*User interface (or, “USE nrutil”):*

```

FUNCTION ifirstloc(mask)
  T, INTENT(IN) :: mask
  INTEGER(I4B) :: ifirstloc
END FUNCTION ifirstloc

```

Applicable types and ranks:

T \equiv any logical type, rank 1

Types and ranks implemented (overloaded) in nrutil:

T \equiv LOGICAL(LGT)

Action:

Returns the index (subscript value) of the first location, in a one-dimensional logical mask, that has the value `.TRUE.`, or returns `size(mask)+1` if all components of mask are `.FALSE.`

Note that while the reference implementation uses a do-loop, the function is parallelized in nrutil by instead using the `merge` and `maxloc` intrinsics.

Reference implementation:

```
INTEGER(I4B) :: i
do i=1,size(mask)
  if (mask(i)) then
    ifirstloc=i
    return
  end if
end do
ifirstloc=i
```

23.3 Argument Checking and Error Handling

It is good programming practice for a routine to check the assumptions (“assertions”) that it makes about the sizes of input arrays, allowed range of numerical arguments, and so forth. The routines `assert` and `assert_eq` are meant for this kind of use. The routine `nrerror` is our default error reporting routine.

★ ★ ★

assert (exit with error message if any assertion is false)

User interface (or, “USE nrutil”):

```
SUBROUTINE assert(n1,n2,...,string)
CHARACTER(LEN=*), INTENT(IN) :: string
LOGICAL, INTENT(IN) :: n1,n2,...
END SUBROUTINE assert
```

Action:

Embedding program dies gracefully with an error message if any of the logical arguments are false. Typical use is with logical expressions as the actual arguments. `nrutil` implements and overloads forms with 1, 2, 3, and 4 logical arguments, plus a form with a vector logical argument,

```
LOGICAL, DIMENSION(:), INTENT(IN) :: n
that is checked by the all(n) intrinsic.
```

Reference implementation:

```

if (.not. (n1.and.n2.and...)) then
  write (*,*) 'nrerror: an assertion failed with this tag:', string
  STOP 'program terminated by assert'
end if

```

★ ★ ★

assert_eq (exit with error message if integer arguments not all equal)*User interface (or, "USE nrutil"):*

```

FUNCTION assert_eq(n1,n2,n3,...,string)
CHARACTER(LEN=*), INTENT(IN) :: string
INTEGER, INTENT(IN) :: n1,n2,n3,...
INTEGER :: assert_eq
END FUNCTION assert_eq

```

Action:

Embedding program dies gracefully with an error message if any of the integer arguments are not equal to the first. Otherwise, return the value of the first argument. Typical use is for enforcing equality on the sizes of arrays passed to a subprogram. `nrutil` implements and overloads forms with 1, 2, 3, and 4 integer arguments, plus a form with a vector integer argument,

```

INTEGER, DIMENSION(:), INTENT(IN) :: n
that is checked by the conditional if (all(nn(2:)==nn(1))).

```

Reference implementation:

```

if (n1==n2.and.n2==n3.and...) then
  assert_eq=n1
else
  write (*,*) 'nrerror: an assert_eq failed with this tag:', string
  STOP 'program terminated by assert_eq'
end if

```

★ ★ ★

nrerror (report error message and stop)*User interface (or, "USE nrutil"):*

```

SUBROUTINE nrerror(string)
CHARACTER(LEN=*), INTENT(IN) :: string
END SUBROUTINE nrerror

```

Action:

This is the minimal error handler used in this book. In applications of any complexity, it is intended only as a placeholder for a user's more complicated error handling strategy.

Reference implementation:

```

write (*,*) 'nrerror: ',string
STOP 'program terminated by nrerror'

```

23.4 Routines for Polynomials and Recurrences

Apart from programming convenience, these routines are designed to allow for nontrivial parallel implementations, as discussed in §22.2 and §22.3.

★ ★ ★

arth (returns arithmetic progression as an array)

User interface (or, “USE nrutil”):

```
FUNCTION arth(first,increment,n)
  T, INTENT(IN) :: first,increment
  INTEGER(I4B), INTENT(IN) :: n
  T, DIMENSION(n) [or, 1 rank higher than T]:: arth
END FUNCTION arth
```

Applicable types and ranks:

T \equiv any numerical type, any rank

Types and ranks implemented (overloaded) in nrutil:

T \equiv INTEGER(I4B), REAL(SP), REAL(DP)

Action:

Returns an array of length **n** containing an arithmetic progression whose first value is **first** and whose increment is **increment**. If **first** and **increment** have rank greater than zero, returns an array of one larger rank, with the last subscript having size **n** and indexing the progressions. Note that the following reference implementation (for the scalar case) is definitional only, and neither parallelized nor optimized for roundoff error. See §22.2 and Appendix C1 for implementation by subvector scaling.

Reference implementation:

```
INTEGER(I4B) :: k
if (n > 0) arth(1)=first
do k=2,n
  arth(k)=arth(k-1)+increment
end do
```

★ ★ ★

geop (returns geometric progression as an array)

User interface (or, “USE nrutil”):

```
FUNCTION geop(first,factor,n)
  T, INTENT(IN) :: first,factor
  INTEGER(I4B), INTENT(IN) :: n
  T, DIMENSION(n) [or, 1 rank higher than T]:: geop
END FUNCTION geop
```

Applicable types and ranks:

T \equiv any numerical type, any rank

Types and ranks implemented (overloaded) in nrutil:

T \equiv INTEGER(I4B), REAL(SP), REAL(DP), REAL(DP)(:),
COMPLEX(SPC)

Action:

Returns an array of length n containing a geometric progression whose first value is `first` and whose multiplier is `factor`. If `first` and `factor` have rank greater than zero, returns an array of one larger rank, with the last subscript having size n and indexing the progression. Note that the following reference implementation (for the scalar case) is definitional only, and neither parallelized nor optimized for roundoff error. See §22.2 and Appendix C1 for implementation by subvector scaling.

Reference implementation:

```

INTEGER(I4B) :: k
if (n > 0) geop(1)=first
do k=2,n
    geop(k)=geop(k-1)*factor
end do

```

* * *

cumsum (cumulative sum on an array, with optional additive seed)

User interface (or, “USE nrutil”):

```

FUNCTION cumsum(arr, seed)
T, DIMENSION(:), INTENT(IN) :: arr
T, OPTIONAL, INTENT(IN) :: seed
T, DIMENSION(size(arr)), INTENT(OUT) :: cumsum
END FUNCTION cumsum

```

Applicable types and ranks:

T \equiv any numerical type

Types and ranks implemented (overloaded) in nrutil:

T \equiv INTEGER(I4B), REAL(SP)

Action:

Given the rank 1 array `arr` of type **T**, returns an array of identical type and size containing the cumulative sums of `arr`. If the optional argument `seed` is present, it is added to the first component (and therefore, by cumulation, all components) of the result. See §22.2 for parallelization ideas.

Reference implementation:

```

INTEGER(I4B) :: n, j
T :: sd
n=size(arr)
if (n == 0) return
sd=0.0
if (present(seed)) sd=seed
cumsum(1)=arr(1)+sd
do j=2,n
    cumsum(j)=cumsum(j-1)+arr(j)
end do

```

* * *

cumprod (cumulative prod on an array, with optional multiplicative seed)

User interface (or, “USE nrutil”):

```

FUNCTION cumprod(arr, seed)
T, DIMENSION(:), INTENT(IN) :: arr
T, OPTIONAL, INTENT(IN) :: seed
T, DIMENSION(size(arr)), INTENT(OUT) :: cumprod
END FUNCTION cumprod

```

Applicable types and ranks:

T \equiv any numerical type

Types and ranks implemented (overloaded) in nrutil:

T \equiv REAL(SP)

Action:

Given the rank 1 array **arr** of type **T**, returns an array of identical type and size containing the cumulative products of **arr**. If the optional argument **seed** is present, it is multiplied into the first component (and therefore, by cumulation, into all components) of the result. See §22.2 for parallelization ideas.

Reference implementation:

```
INTEGER(I4B) :: n,j
T :: sd
n=size(arr)
if (n == 0) return
sd=1.0
if (present(seed)) sd=seed
cumprod(1)=arr(1)*sd
do j=2,n
    cumprod(j)=cumprod(j-1)*arr(j)
end do
```

* * *

poly (polynomial evaluation)

User interface (or, “USE nrutil”):

```
FUNCTION poly(x,coeffs,mask)
T,, DIMENSION(:,...), INTENT(IN) :: x
T, DIMENSION(:), INTENT(IN) :: coeffs
LOGICAL(LGT), DIMENSION(:,...), OPTIONAL, INTENT(IN) :: mask
T :: poly
END FUNCTION poly
```

Applicable types and ranks:

T \equiv any numerical type (**x** may be scalar or have any rank; **x** and **coeffs** may have different numerical types)

Types and ranks implemented (overloaded) in nrutil:

T \equiv various combinations of REAL(SP), REAL(SP)(:), REAL(DP), REAL(DP)(:), COMPLEX(SPC) (see Appendix C1 for details)

Action:

Returns a scalar value or array with the same type and shape as **x**, containing the result of evaluating the polynomial with one-dimensional coefficient vector **coeffs** on each component of **x**. The optional argument **mask**, if present, has the same shape as **x**, and suppresses evaluation of the polynomial where its components are **.false..** The following reference code shows the case where **mask** is not present. (The other case can be included by overloading.)

Reference implementation:

```

INTEGER(I4B) :: i,n
n=size(coeffs)
if (n <= 0) then
  poly=0.0
else
  poly=coeffs(n)
  do i=n-1,1,-1
    poly=x*poly+coeffs(i)
  end do
end if

```

★ ★ ★

poly_term (partial cumulants of a polynomial)

User interface (or, “USE nrutil”):

```

FUNCTION poly_term(a,x)
  T, DIMENSION(:), INTENT(IN) :: a
  T, INTENT(IN) :: x
  T, DIMENSION(size(a)) :: poly_term
END FUNCTION poly_term

```

Applicable types and ranks:

T \equiv any numerical type

Types and ranks implemented (overloaded) in nrutil:

T \equiv REAL(SP), COMPLEX(SPC)

Action:

Returns an array of type and size the same as the one-dimensional array *a*, containing the partial cumulants of the polynomial with coefficients *a* (arranged from highest-order to lowest-order coefficients, n.b.) evaluated at *x*. This is equivalent to synthetic division, and can be parallelized. See §22.3. Note that the order of arguments is reversed in *poly* and *poly_term* — each routine returns a value with the size and shape of the *first* argument, the usual Fortran 90 convention.

Reference implementation:

```

INTEGER(I4B) :: n,j
n=size(a)
if (n <= 0) return
poly_term(1)=a(1)
do j=2,n
  poly_term(j)=a(j)+x*poly_term(j-1)
end do

```

★ ★ ★

zroots_unity (returns powers of complex *n*th root of unity)

User interface (or, “USE nrutil”):

```

FUNCTION zroots_unity(n,nn)
  INTEGER(I4B), INTENT(IN) :: n,nn
  COMPLEX(SPC), DIMENSION(nn) :: zroots_unity
END FUNCTION zroots_unity

```

Action:

Returns a complex array containing *nn* consecutive powers of the *nth* complex root of unity. Note that the following reference implementation is definitional only, and neither parallelized nor optimized for roundoff error. See Appendix C1 for implementation by subvector scaling.

Reference implementation:

```

INTEGER(I4B) :: k
REAL(SP) :: theta
if (nn==0) return
zroots_unity(1)=1.0
if (nn==1) return
theta=TWOPI/n
zroots_unity(2)=cmplx(cos(theta),sin(theta))
do k=3,nn
  zroots_unity(k)=zroots_unity(k-1)*zroots_unity(2)
end do

```

23.5 Routines for Outer Operations on Vectors

Outer operations on vectors take two vectors as input, and return a matrix as output. One dimension of the matrix is the size of the first vector, the other is the size of the second vector. Our convention is always the standard one,

$$\text{result}(i,j) = \text{first_operand}(i) \text{ (op) } \text{second_operand}(j)$$

where (*op*) is any of addition, subtraction, multiplication, division, and logical and. The reason for coding these as utility routines is that Fortran 90's native construction, with two spreads (cf. §22.1), is difficult to read and thus prone to programmer errors.

★ ★ ★

outerprod (outer product)

User interface (or, "USE nrutil"):

```

FUNCTION outerprod(a,b)
  T, DIMENSION(:), INTENT(IN) :: a,b
  T, DIMENSION(size(a),size(b)) :: outerprod
END FUNCTION outerprod

```

Applicable types and ranks:

T ≡ any numerical type

Types and ranks implemented (overloaded) in nrutil:

T ≡ REAL(SP), REAL(DP)

Action:

Returns a matrix that is the outer product of two vectors.

Reference implementation:

```

outerprod = spread(a,dim=2,ncopies=size(b)) * &
  spread(b,dim=1,ncopies=size(a))

```

★ ★ ★

outerdiv (outer quotient)*User interface (or, “USE nrutil”):*

```

FUNCTION outerdiv(a,b)
  T, DIMENSION(:), INTENT(IN) :: a,b
  T, DIMENSION(size(a),size(b)) :: outerdiv
END FUNCTION outerdiv

```

*Applicable types and ranks:***T** \equiv any numerical type*Types and ranks implemented (overloaded) in nrutil:***T** \equiv REAL(SP)*Action:*

Returns a matrix that is the outer quotient of two vectors.

Reference implementation:

```

outerdiv = spread(a,dim=2,ncopies=size(b)) / &
           spread(b,dim=1,ncopies=size(a))

```

★ ★ ★

outersum (outer sum)*User interface (or, “USE nrutil”):*

```

FUNCTION outersum(a,b)

```

*Applicable types and ranks:***T** \equiv any numerical type*Types and ranks implemented (overloaded) in nrutil:***T** \equiv REAL(SP)*Action:*

Returns a matrix that is the outer sum of two vectors.

Reference implementation:

```

outersum = spread(a,dim=2,ncopies=size(b)) + &
           spread(b,dim=1,ncopies=size(a))

```

★ ★ ★

outerdiff (outer difference)*User interface (or, “USE nrutil”):*

```

FUNCTION outerdiff(a,b)
  T, DIMENSION(:), INTENT(IN) :: a,b
  T, DIMENSION(size(a),size(b)) :: outerdiff
END FUNCTION outerdiff

```

*Applicable types and ranks:***T** \equiv any numerical type*Types and ranks implemented (overloaded) in nrutil:***T** \equiv INTEGER(I4B), REAL(SP), REAL(DP)*Action:*

Returns a matrix that is the outer difference of two vectors.

Reference implementation:

```
outerdiff = spread(a,dim=2,ncopies=size(b)) - &
           spread(b,dim=1,ncopies=size(a))
```

★ ★ ★

outerand (outer logical and)

User interface (or, “USE nrutil”):

```
FUNCTION outerand(a,b)
  LOGICAL(LGT), DIMENSION(:), INTENT(IN) :: a,b
  LOGICAL(LGT), DIMENSION(size(a),size(b)) :: outerand
END FUNCTION outerand
```

Applicable types and ranks:

T \equiv any logical type

Types and ranks implemented (overloaded) in nrutil:

T \equiv LOGICAL (LGT)

Action:

Returns a matrix that is the outer logical and of two vectors.

Reference implementation:

```
outerand = spread(a,dim=2,ncopies=size(b)) .and. &
           spread(b,dim=1,ncopies=size(a))
```

23.6 Routines for Scatter with Combine

These are common parallel functions that Fortran 90 simply doesn't provide a means for implementing. If you have a parallel machine, you should substitute library routines specific to your hardware.

★ ★ ★

scatter_add (scatter-add source to specified components of destination)

User interface (or, “USE nrutil”):

```
SUBROUTINE scatter_add(dest,source,dest_index)
  T, DIMENSION(:), INTENT(OUT) :: dest
  T, DIMENSION(:), INTENT(IN) :: source
  INTEGER(I4B), DIMENSION(:), INTENT(IN) :: dest_index
END SUBROUTINE scatter_add
```

Applicable types and ranks:

T \equiv any numerical type

Types and ranks implemented (overloaded) in nrutil:

T \equiv REAL (SP), REAL (DP)

Action:

Adds each component of the array `source` into a component of `dest` specified by the index array `dest_index`. (The user will usually have zeroed `dest` before the call to this routine.) Note that `dest_index` has the size of `source`, but must contain values in the range from 1 to `size(dest)`, inclusive. Out-of-range values are ignored. There is no parallel implementation of this routine accessible from Fortran 90; most parallel machines supply an implementation as a library routine.

Reference implementation:

```

INTEGER(I4B) :: m,n,j,i
n=assert_eq(size(source),size(dest_index),'scatter_add')
m=size(dest)
do j=1,n
  i=dest_index(j)
  if (i > 0 .and. i <= m) dest(i)=dest(i)+source(j)
end do

```

★ ★ ★

scatter_max (scatter-max source to specified components of destination)*User interface (or, "USE nrutil"):*

```

SUBROUTINE scatter_max(dest,source,dest_index)
  T, DIMENSION(:), INTENT(OUT) :: dest
  T, DIMENSION(:), INTENT(IN) :: source
  INTEGER(I4B), DIMENSION(:), INTENT(IN) :: dest_index
END SUBROUTINE scatter_max

```

Applicable types and ranks:

T \equiv any integer or real type

Types and ranks implemented (overloaded) in nrutil:

T \equiv REAL(SP), REAL(DP)

Action:

Takes the max operation between each component of the array `source` and a component of `dest` specified by the index array `dest_index`, replacing that component of `dest` with the value obtained ("maxing into" operation). (The user will often want to fill the array `dest` with the value `-huge` before the call to this routine.) Note that `dest_index` has the size of `source`, but must contain values in the range from 1 to `size(dest)`, inclusive. Out-of-range values are ignored. There is no parallel implementation of this routine accessible from Fortran 90; most parallel machines supply an implementation as a library routine.

Reference implementation:

```

INTEGER(I4B) :: m,n,j,i
n=assert_eq(size(source),size(dest_index),'scatter_max')
m=size(dest)
do j=1,n
  i=dest_index(j)
  if (i > 0 .and. i <= m) dest(i)=max(dest(i),source(j))
end do

```

23.7 Routines for Skew Operations on Matrices

These are also missing parallel capabilities in Fortran 90. In Appendix C1 they are coded serially, with one or more do-loops.

★ ★ ★

diagadd (adds vector to diagonal of a matrix)

User interface (or, “USE nrutil”):

```
SUBROUTINE diagadd(mat,diag)
  T, DIMENSION(:,,:), INTENT(INOUT) :: mat
  T, DIMENSION(:), INTENT(IN) :: diag
END SUBROUTINE diagadd
```

Applicable types and ranks:

T \equiv any numerical type

Types and ranks implemented (overloaded) in nrutil:

T \equiv REAL(SP)

Action:

The argument *diag*, either a scalar or else a vector whose size must be the smaller of the two dimensions of matrix *mat*, is added to the diagonal of the matrix *mat*. The following shows an implementation where *diag* is a vector; the scalar case can be overloaded (see Appendix C1).

Reference implementation:

```
INTEGER(I4B) :: j,n
n = assert_eq(size(diag),min(size(mat,1),size(mat,2)),'diagadd')
do j=1,n
  mat(j,j)=mat(j,j)+diag(j)
end do
```

★ ★ ★

diagmult (multiplies vector into diagonal of a matrix)

User interface (or, “USE nrutil”):

```
SUBROUTINE diagmult(mat,diag)
  T, DIMENSION(:,,:), INTENT(INOUT) :: mat
  T, DIMENSION(:), INTENT(IN) :: diag
END SUBROUTINE diagmult
```

Applicable types and ranks:

T \equiv any numerical type

Types and ranks implemented (overloaded) in nrutil:

T \equiv REAL(SP)

Action:

The argument *diag*, either a scalar or else a vector whose size must be the smaller of the two dimensions of matrix *mat*, is multiplied onto the diagonal of the matrix *mat*. The following shows an implementation where *diag* is a vector; the scalar case can be overloaded (see Appendix C1).

Reference implementation:

```
INTEGER(I4B) :: j,n
n = assert_eq(size(diag),min(size(mat,1),size(mat,2)), 'diagmult')
do j=1,n
    mat(j,j)=mat(j,j)*diag(j)
end do
```

★ ★ ★

get_diag (gets diagonal of matrix)

User interface (or, “USE nrutil”):

```
FUNCTION get_diag(mat)
T, DIMENSION(:,,:), INTENT(IN) :: mat
T, DIMENSION(min(size(mat,1),size(mat,2))) :: get_diag
END FUNCTION get_diag
```

Applicable types and ranks:

T \equiv any type

Types and ranks implemented (overloaded) in nrutil:

T \equiv REAL(SP), REAL(DP)

Action:

Returns a vector containing the diagonal values of the matrix mat.

Reference implementation:

```
INTEGER(I4B) :: j
do j=1,min(size(mat,1),size(mat,2))
    get_diag(j)=mat(j,j)
end do
```

★ ★ ★

put_diag (sets the diagonal elements of a matrix)

User interface (or, “USE nrutil”):

```
SUBROUTINE put_diag(diag,mat)
T, DIMENSION(:), INTENT(IN) :: diag
T, DIMENSION(:,,:), INTENT(INOUT) :: mat
END SUBROUTINE put_diag
```

Applicable types and ranks:

T \equiv any type

Types and ranks implemented (overloaded) in nrutil:

T \equiv REAL(SP)

Action:

Sets the diagonal of matrix mat equal to the argument diag, either a scalar or else a vector whose size must be the smaller of the two dimensions of matrix mat. The following shows an implementation where diag is a vector; the scalar case can be overloaded (see Appendix C1).

Reference implementation:

```
INTEGER(I4B) :: j,n
n=assert_eq(size(diag),min(size(mat,1),size(mat,2)), 'put_diag')
do j=1,n
    mat(j,j)=diag(j)
end do
```

★ ★ ★

unit_matrix (returns a unit matrix)*User interface (or, “USE nrutil”):*

```

SUBROUTINE unit_matrix(mat)
  T, DIMENSION(:,,:), INTENT(OUT) :: mat
END SUBROUTINE unit_matrix

```

*Applicable types and ranks:***T** \equiv any numerical type*Types and ranks implemented (overloaded) in nrutil:***T** \equiv REAL (SP)*Action:*

Sets the diagonal components of **mat** to unity, all other components to zero. When **mat** is square, this will be the unit matrix; otherwise, a unit matrix with appended rows or columns of zeros.

Reference implementation:

```

INTEGER(I4B) :: i,n
n=min(size(mat,1),size(mat,2))
mat(:,:)=0.0
do i=1,n
  mat(i,i)=1.0
end do

```

★ ★ ★

upper_triangle (returns an upper triangular mask)*User interface (or, “USE nrutil”):*

```

FUNCTION upper_triangle(j,k,extra)
  INTEGER(I4B), INTENT(IN) :: j,k
  INTEGER(I4B), OPTIONAL, INTENT(IN) :: extra
  LOGICAL(LGT), DIMENSION(j,k) :: upper_triangle
END FUNCTION upper_triangle

```

Action:

When the optional argument **extra** is zero or absent, returns a logical mask of shape **(j,k)** whose values are true above and to the right of the diagonal, false elsewhere (including on the diagonal). When **extra** is present and positive, a corresponding number of additional (sub-)diagonals are returned as true. (**extra** = 1 makes the main diagonal return true.) When **extra** is present and negative, it suppresses a corresponding number of superdiagonals.

Reference implementation:

```

INTEGER(I4B) :: n,jj,kk
n=0
if (present(extra)) n=extra
do jj=1,j
  do kk=1,k
    upper_triangle(jj,kk)= (jj-kk < n)
  end do
end do

```

★ ★ ★

lower_triangle (returns a lower triangular mask)*User interface (or, “USE nrutil”):*

```

FUNCTION lower_triangle(j,k,extra)
  INTEGER(I4B), INTENT(IN) :: j,k
  INTEGER(I4B), OPTIONAL, INTENT(IN) :: extra
  LOGICAL(LGT), DIMENSION(j,k) :: lower_triangle
END FUNCTION lower_triangle

```

Action:

When the optional argument *extra* is zero or absent, returns a logical mask of shape (j,k) whose values are true below and to the left of the diagonal, false elsewhere (including on the diagonal). When *extra* is present and positive, a corresponding number of additional (super-)diagonals are returned as true. (*extra* = 1 makes the main diagonal return true.) When *extra* is present and negative, it suppresses a corresponding number of subdiagonals.

Reference implementation:

```

INTEGER(I4B) :: n,jj,kk
n=0
if (present(extra)) n=extra
do jj=1,j
  do kk=1,k
    lower_triangle(jj,kk)= (kk-jj < n)
  end do
end do

```

Fortran 95’s *forall* construction will make the parallel implementation of all our skew operations utilities extremely simple. For example, the *do-loop* in *diagadd* will collapse to

```
forall (j=1:n) mat(j,j)=mat(j,j)+diag(j)
```

In fact, this implementation is so simple as to raise the question of whether a separate utility like *diagadd* will be needed at all. There are valid arguments on both sides of this question: The “con” argument, against a routine like *diagadd*, is that it is just another reserved name that you have to remember (if you want to use it). The “pro” argument is that a separate routine avoids the “index pollution” (the opposite disease from “index loss” discussed in §22.1) of introducing a superfluous variable *j*, and that a separate utility allows for additional error checking on the sizes and compatibility of its arguments. We expect that different programmers will have differing tastes.

The argument for keeping a routine like *upper_triangle* or *lower_triangle*, once Fortran 95’s *masked forall* constructions become available, is less persuasive. We recommend that you consider these two routines as placeholders for “remember to recode this in Fortran 95, someday.”

23.8 Other Routine(s)

You might argue that we don’t really need a routine for the idiom

```
sqrt(dot_product(v,v))
```

You might be right. The ability to overload the complex case, with its additional complex conjugate, is an argument in its favor, however.

★ ★ ★

vabs (L_2 norm of a vector)

User interface (or, “USE nrutil”):

```
FUNCTION vabs(v)
  T, DIMENSION(:), INTENT(IN) :: v
  T :: vabs
END FUNCTION vabs
```

Applicable types and ranks:

T \equiv any real or complex type

Types and ranks implemented (overloaded) in nrutil:

T \equiv REAL(SP)

Action:

Returns the length of a vector v in L_2 norm, that is, the square root of the sum of the squares of the components. (For complex types, the `dot_product` should be between the vector and its complex conjugate.)

Reference implementation:

```
vabs=sqrt(dot_product(v,v))
```

Fortran 90 Code Chapters B1–B20

Fortran 90 versions of all the Numerical Recipes routines appear in the following Chapters B1 through B20, numbered in correspondence with Chapters 1 through 20 in Volume 1. Within each chapter, the routines appear in the same order as in Volume 1, but not broken out separately by section number within Volume 1’s chapters.

There are commentaries accompanying many of the routines, generally following the printed listing of the routine to which they apply. These are of two kinds: issues related to parallelizing the algorithm in question, and issues related to the Fortran 90 implementation. To distinguish between these two, rather different, kinds of discussions, we use the two icons,

the left icon (above) indicating a “parallel note,” and the right icon denoting a “Fortran 90 tip.” Specific code segments of the routine that are discussed in these commentaries are singled out by reproducing some of the code as an “index line” next to the icon, or at the beginning of subsequent paragraphs if there are several items that are commented on.

`d=merge(FPMIN,d,abs(d)<FPMIN)` This would be the start of a discussion of code that begins at the line in the listing containing the indicated code fragment.

★ ★ ★

A row of stars, like the above, is used between unrelated routines, or at the beginning and end of related groups of routines.

Some chapters contain discussions that are more general than commentary on individual routines, but that were deemed too specific for inclusion in Chapters 21 through 23. Here are some highlights of this additional material:

- Approximations to roots of orthogonal polynomials for parallel computation of Gaussian quadrature formulas (Chapter B4)
- Difficulty of, and tricks for, parallel calculation of special function values in a SIMD model of computation (Chapter B6)
- Parallel random number generation (Chapter B7)
- Fortran 90 tricks for dealing with ties in sorted arrays, counting things in boxes, etc. (Chapter B14)
- Use of recursion in implementing multigrid elliptic PDE solvers (Chapter B19)

Chapter B1. Preliminaries

```

SUBROUTINE flmoon(n,nph,jd,frac)
USE nrtype; USE nrutil, ONLY : nrerror
IMPLICIT NONE
INTEGER(I4B), INTENT(IN) :: n,nph
INTEGER(I4B), INTENT(OUT) :: jd
REAL(SP), INTENT(OUT) :: frac
    Our programs begin with an introductory comment summarizing their purpose and explaining
    their calling sequence. This routine calculates the phases of the moon. Given an integer
    n and a code nph for the phase desired (nph = 0 for new moon, 1 for first quarter, 2 for
    full, 3 for last quarter), the routine returns the Julian Day Number jd, and the fractional
    part of a day frac to be added to it, of the nth such phase since January, 1900. Greenwich
    Mean Time is assumed.
REAL(SP), PARAMETER :: RAD=PI/180.0_sp
INTEGER(I4B) :: i
REAL(SP) :: am,as,c,t,t2,xtra
c=n+nph/4.0_sp
t=c/1236.85_sp
t2=t**2
as=359.2242_sp+29.105356_sp*c
am=306.0253_sp+385.816918_sp*c+0.010730_sp*t2
jd=2415020+28*n+7*nph
xtra=0.75933_sp+1.53058868_sp*c+(1.178e-4_sp-1.55e-7_sp*t)*t2
select case(nph)
    case(0,2)
        xtra=xtra+(0.1734_sp-3.93e-4_sp*t)*sin(RAD*as)-0.4068_sp*sin(RAD*am)
    case(1,3)
        xtra=xtra+(0.1721_sp-4.0e-4_sp*t)*sin(RAD*as)-0.6280_sp*sin(RAD*am)
    case default
        call nrerror('flmoon: nph is unknown')
end select
i=int(merge(xtra,xtra-1.0_sp, xtra >= 0.0))
jd=jd+i
frac=xtra-i
END SUBROUTINE flmoon

```

This is how we comment an individual line.

You aren't really intended to understand this algorithm, but it does work!

This is how we will indicate error conditions.

f90 `select case(nph)...case(0,2)...end select` Fortran 90 includes a case construction that executes at most one of several blocks of code, depending on the value of an integer, logical, or character expression. Ideally, the case construction will execute more efficiently than a long sequence of cascaded `if...else if...else if...` constructions. C programmers should note that the Fortran 90 construction, perhaps mercifully, does not have C's “drop-through” feature.

`merge(xtra,xtra-1.0_sp, xtra >= 0.0)` The merge construction in Fortran 90, while intended primarily for use with vector arguments, is also a convenient way of generating conditional scalar expressions, that is, expressions with one value, or another, depending on the result of a logical test.

When the arguments of a merge are vectors, parallelization by the compiler is straightforward as an array parallel operation (see p. 964).

Less obvious is how the scalar case, as above, is handled. For small-scale parallel (SSP) machines, the natural gain is via speculative evaluation of both of the first two arguments simultaneously with evaluation of the test.

A good compiler should not penalize a scalar machine for use of either the scalar or vector merge construction. The Fortran 90 standard states that “it is not necessary for a processor to evaluate all of the operands of an expression, or to evaluate entirely each operand, if the value of the expression can be determined otherwise.” Therefore, for each test on a scalar machine, only one or the other of the first two argument components need be evaluated.

```

FUNCTION julday(mm,id,iyyy)
USE nrtype; USE nrutil, ONLY : nrerror
IMPLICIT NONE
INTEGER(I4B), INTENT(IN) :: mm,id,iyyy
INTEGER(I4B) :: julday
  In this routine julday returns the Julian Day Number that begins at noon of the calendar
  date specified by month mm, day id, and year iyyy, all integer variables. Positive year
  signifies A.D.; negative, B.C. Remember that the year after 1 B.C. was 1 A.D.
  INTEGER(I4B), PARAMETER :: IGREG=15+31*(10+12*1582)    Gregorian Calendar adopted
  INTEGER(I4B) :: ja,jm,jy                                Oct. 15, 1582.
  jy=iyyy
  if (jy == 0) call nrerror('julday: there is no year zero')
  if (jy < 0) jy=jy+1
  if (mm > 2) then
    jm=mm+1
  else
    jy=jy-1
    jm=mm+13
  end if
  julday=floor(365.25_sp*jy)+floor(30.6001_sp*jm)+id+1720995
  if (id+31*(mm+12*iyyy) >= IGREG) then
    ja=floor(0.01_sp*jy)
    julday=julday+2-ja+floor(0.25_sp*ja)
  end if
END FUNCTION julday

```

Here is an example of a block IF-structure.

Test whether to change to Gregorian Calendar.

★ ★ ★

```

PROGRAM badluk
USE nrtype
USE nr, ONLY : flmoon,julday
IMPLICIT NONE
INTEGER(I4B) :: ic,icon,idwk,ifrac,im,iyyy,jd,jday,n
INTEGER(I4B) :: iybeg=1900,iyend=2000    The range of dates to be searched.
REAL(SP) :: frac
REAL(SP), PARAMETER :: TIMZON=-5.0_sp/24.0_sp
  Time zone -5 is Eastern Standard Time.
write (*, '(1x,a,i5,a,i5)') 'Full moons on Friday the 13th from', &
  iybeg, ' to', iyend
do iyyy=iybeg,iyend
  do im=1,12
    jday=julday(im,13,iyyy)
    idwk=mod(jday+1,7)

```

Loop over each year,
and each month.
Is the 13th a Friday?

```

if (idwk == 5) then
  n=12.37_sp*(iyyy-1900+(im-0.5_sp)/12.0_sp)
  This value n is a first approximation to how many full moons have occurred
  since 1900. We will feed it into the phase routine and adjust it up or down until
  we determine that our desired 13th was or was not a full moon. The variable
  icon signals the direction of adjustment.
  icon=0
  do
    call flmoon(n,2,jd,frac)      Get date of full moon n.
    ifrac=nint(24.0_sp*(frac+TIMZON))  Convert to hours in correct time
    if (ifrac < 0) then            zone.
      jd=jd-1                    Convert from Julian Days beginning at noon
      ifrac=ifrac+24              to civil days beginning at midnight.
    end if
    if (ifrac > 12) then
      jd=jd+1
      ifrac=ifrac-12
    else
      ifrac=ifrac+12
    end if
    if (jd == jday) then          Did we hit our target day?
      write (*, '(1x,i2,a,i2,a,i4)') im, '/', 13, '/', iyyy
      write (*, '(1x,a,i2,a)') 'Full moon ', ifrac, &
        ' hrs after midnight (EST).'
      Don't worry if you are unfamiliar with FORTRAN's esoteric input/output
      statements; very few programs in this book do any input/output.
      exit                      Part of the break-structure, case of a match.
    else                          Didn't hit it.
      ic=isign(1,jday-jd)
      if (ic == -icon) exit      Another break, case of no match.
      icon=ic
      n=n+ic
    end if
  end do
end if
end do
END PROGRAM badluk

```

f90 ...IGREG=15+31*(10+12*1582) (in julday), ...TIMZON=-5.0_sp/24.0_sp (in badluk) These are two examples of initialization expressions for “named constants” (that is, PARAMETERS). Because the initialization expressions will generally be evaluated at compile time, Fortran 90 puts some restrictions on what kinds of intrinsic functions they can contain. Although the evaluation of a real expression like $-5.0_sp/24.0_sp$ *ought* to give identical results at compile time and at execution time, all the way down to the least significant bit, in our opinion the conservative programmer shouldn’t count on strict identity at the level of floating-point roundoff error. (In the special case of *cross*-compilers, such roundoff-level discrepancies between compile time and run time are almost inevitable.)

```

SUBROUTINE caldat(julian,mm,id,iyyy)
USE nrtype
IMPLICIT NONE
INTEGER(I4B), INTENT(IN) :: julian
INTEGER(I4B), INTENT(OUT) :: mm,id,iyyy
    Inverse of the function julday given above. Here julian is input as a Julian Day Number,
    and the routine outputs mm,id, and iyyy as the month, day, and year on which the specified
    Julian Day started at noon.
INTEGER(I4B) :: ja,jalpha,jb,jc,jd,je
INTEGER(I4B), PARAMETER :: IGREG=2299161
if (julian >= IGREG) then
    Cross-over to Gregorian Calendar produces this
    jalpha=int(((julian-1867216)-0.25_dp)/36524.25_dp) correction.

Chapter B2. Solution of Linear Algebraic Equations

```

SUBROUTINE gaussj(a,b)
USE nrtype; USE nrutil, ONLY : assert_eq,nrerror,outerand,outerprod,swap
IMPLICIT NONE
REAL(SP), DIMENSION(:,,:), INTENT(INOUT) :: a,b
    Linear equation solution by Gauss-Jordan elimination, equation (2.1.1). a is an  $N \times N$  input
    coefficient matrix. b is an  $N \times M$  input matrix containing  $M$  right-hand-side vectors. On
    output, a is replaced by its matrix inverse, and b is replaced by the corresponding set of
    solution vectors.
INTEGER(I4B), DIMENSION(size(a,1)) :: ipiv,indxr,indxc
    These arrays are used for bookkeeping on the pivoting.
LOGICAL(LGT), DIMENSION(size(a,1)) :: lpiv
REAL(SP) :: pivinv
REAL(SP), DIMENSION(size(a,1)) :: dumc
INTEGER(I4B), TARGET :: irc(2)
INTEGER(I4B) :: i,l,n
INTEGER(I4B), POINTER :: irow,icol
n=assert_eq(size(a,1),size(a,2),size(b,1),'gaussj')
irow => irc(1)
icol => irc(2)
ipiv=0
do i=1,n
    Main loop over columns to be reduced.
    lpiv = (ipiv == 0)          Begin search for a pivot element.
    irc=maxloc(abs(a),outerand(lpiv,lpiv))
    ipiv(icol)=ipiv(icol)+1
    if (ipiv(icol) > 1) call nrerror('gaussj: singular matrix (1)')
    We now have the pivot element, so we interchange rows, if needed, to put the pivot
    element on the diagonal. The columns are not physically interchanged, only relabeled:
    indxc(i), the column of the ith pivot element, is the ith column that is reduced, while
    indxr(i) is the row in which that pivot element was originally located. If  $\text{indxr}(i) \neq$ 
    indxc(i) there is an implied column interchange. With this form of bookkeeping, the
    solution b's will end up in the correct order, and the inverse matrix will be scrambled
    by columns.
    if (irow /= icol) then
        call swap(a(irow,:),a(icol,:))
        call swap(b(irow,:),b(icol,:))
    end if
    indxr(i)=irow          We are now ready to divide the pivot row by the pivot
    indxc(i)=icol          element, located at irow and icol.
    if (a(icol,icol) == 0.0) &
        call nrerror('gaussj: singular matrix (2)')
    pivinv=1.0_sp/a(icol,icol)
    a(icol,icol)=1.0
    a(icol,:)=a(icol,:)*pivinv
    b(icol,:)=b(icol,:)*pivinv
    dumc=a(:,icol)
    a(:,icol)=0.0          Next, we reduce the rows, except for the pivot one, of
                           course.

```

```

a(icol,icol)=pivinv
a(1:icol-1,:)=a(1:icol-1,:)-outerprod(dumc(1:icol-1),a(icol,:))
b(1:icol-1,:)=b(1:icol-1,:)-outerprod(dumc(1:icol-1),b(icol,:))
a(icol+1,:)=a(icol+1,:)-outerprod(dumc(icol+1:),a(icol,:))
b(icol+1,:)=b(icol+1,:)-outerprod(dumc(icol+1:),b(icol,:))
end do
  It only remains to unscramble the solution in view of the column interchanges. We do this
  by interchanging pairs of columns in the reverse order that the permutation was built up.
do l=n,1,-1
  call swap(a(:,indx(l)),a(:,indxc(l)))
end do
END SUBROUTINE gaussj

```

 **90** irow => irc(1) ... icol => irc(2) The `maxloc` intrinsic returns the location of the maximum value of an array as an integer array, in this case of size 2. Pre-pointing pointer variables to components of the array that will be thus set makes possible convenient references to the desired row and column positions.

`irc=maxloc(abs(a),outerand(lpiv,lpiv))` The combination of `maxloc` and one of the `outer...` routines from `nrutil` allows for a very concise formulation. If this task is done with loops, it becomes the ungainly “flying vee,”

```

aa=0.0
do i=1,n
  if (lpiv(i)) then
    do j=1,n
      if (lpiv(j)) then
        if (abs(a(i,j)) > aa) then
          aa=abs(a(i,j))
          irow=i
          icol=j
        endif
      endif
    end do
  end do
end do

```

`call swap(a(irow,:),a(icol,:))` The `swap` routine (in `nrutil`) is concise and convenient. Fortran 90's ability to overload multiple routines onto a single name is vital here: Much of the convenience would vanish if we had to remember variant routine names for each variable type and rank of object that might be swapped.

Even better, here, than overloading would be if Fortran 90 allowed user-written *elemental* procedures (procedures with unspecified or arbitrary rank and shape), like the intrinsic elemental procedures built into the language. Fortran 95 will, but Fortran 90 doesn't.

One quick (if superficial) test for how much parallelism is achieved in a Fortran 90 routine is to count its `do`-loops, and compare that number to the number of `do`-loops in the Fortran 77 version of the same routine. Here, in `gaussj`, 13 `do`-loops are reduced to 2.

```

a(1:icol-1,:)=... b(1:icol-1,:)=...
a(icol+1,:)=... b(icol+1,:)=...

```

Here the same operation is applied to every row of *a*, and to every row of *b*, *except* row number *icol*. On a massively multiprocessor (MMP) machine it would be better to use a logical mask and do all of *a* in a single statement, all of *b* in another one. For a small-scale parallel (SSP) machine, the lines as written should saturate the machine's concurrency, and they avoid the additional overhead of testing the mask.

This would be a good place to point out, however, that linear algebra routines written in Fortran 90 are likely *never* to be competitive with the hand-coded library routines that are generally supplied as part of MMP programming environments. If you are using our routines instead of library routines written specifically for your architecture, you are wasting cycles!

```

SUBROUTINE ludcmp(a,indx,d)
USE nrttype; USE nrutil, ONLY : assert_eq,imaxloc,nrerror,outerprod,swap
IMPLICIT NONE
REAL(SP), DIMENSION(:,:) , INTENT(INOUT) :: a
INTEGER(I4B), DIMENSION(:), INTENT(OUT) :: indx
REAL(SP), INTENT(OUT) :: d
    Given an  $N \times N$  input matrix a, this routine replaces it by the LU decomposition of a
    rowwise permutation of itself. On output, a is arranged as in equation (2.3.14); indx is an
    output vector of length N that records the row permutation effected by the partial pivoting;
    d is output as  $\pm 1$  depending on whether the number of row interchanges was even or odd,
    respectively. This routine is used in combination with lubksb to solve linear equations or
    invert a matrix.
REAL(SP), DIMENSION(size(a,1)) :: vv          vv stores the implicit scaling of each row.
REAL(SP), PARAMETER :: TINY=1.0e-20_sp        A small number.
INTEGER(I4B) :: j,n,imax
n=assert_eq(size(a,1),size(a,2),size(indx),'ludcmp')
d=1.0                                           No row interchanges yet.
vv=maxval(abs(a),dim=2)                       Loop over rows to get the implicit scaling
if (any(vv == 0.0)) call nrerror('singular matrix in ludcmp') information.
    There is a row of zeros.
vv=1.0_sp/vv                                   Save the scaling.
do j=1,n
    imax=(j-1)+imaxloc(vv(j:n)*abs(a(j:n,j)))  Find the pivot row.
    if (j /= imax) then                        Do we need to interchange rows?
        call swap(a(imax,:),a(j,:))          Yes, do so...
        d=-d                                  ...and change the parity of d.
        vv(imax)=vv(j)                       Also interchange the scale factor.
    end if
    indx(j)=imax
    if (a(j,j) == 0.0) a(j,j)=TINY
        If the pivot element is zero the matrix is singular (at least to the precision of the al-
        gorithm). For some applications on singular matrices, it is desirable to substitute TINY
        for zero.
    a(j+1:n,j)=a(j+1:n,j)/a(j,j)              Divide by the pivot element.
    a(j+1:n,j+1:n)=a(j+1:n,j+1:n)-outerprod(a(j+1:n,j),a(j,j+1:n))
        Reduce remaining submatrix.
end do
END SUBROUTINE ludcmp

```

f90

`vv=maxval(abs(a),dim=2)` A single statement finds the maximum absolute value in each row. Fortran 90 intrinsics like `maxval` generally “do their thing” in the dimension specified by *dim* and return a result with a shape corresponding to the *other* dimensions. Thus, here, *vv*'s size is that of the *first* dimension of *a*.

`imax=(j-1)+imaxloc(vv(j:n)*abs(a(j:n,j)))` Here we see why the `nrutil` routine `imaxloc` is handy: We want the index, in the range 1:n of a quantity to be searched for only in the limited range j:n. Using `imaxloc`, we just add back the proper offset of j-1. (Using only Fortran 90 intrinsics, we could write `imax=(j-1)+sum(maxloc(vv(j:n)*abs(a(j:n,j))))`, but the use of `sum` just to turn an array of length 1 into a scalar seems sufficiently confusing as to be avoided.)

`a(j+1:n,j+1:n)=a(j+1:n,j+1:n)-outerprod(a(j+1:n,j),a(j,j+1:n))`

The Fortran 77 version of `ludcmp`, using Crout's algorithm for the reduction, does not parallelize well: The elements are updated by $O(N^2)$ separate dot product operations in a particular order. Here we use a slightly different reduction, termed "outer product Gaussian elimination" by Golub and Van Loan [1], that requires just N steps of matrix-parallel reduction. (See their §3.2.3 and §3.2.9 for the algorithm, and their §3.4.1 to understand how the pivoting is performed.)

We use `nrutil`'s routine `outerprod` instead of the more cumbersome pure Fortran 90 construction:

```
spread(a(j+1:n,j),dim=2,ncopies=n-j)*spread(a(j,j+1:n),dim=1,ncopies=n-j)
```

```
SUBROUTINE lubksb(a,indx,b)
USE nrtype; USE nrutil, ONLY : assert_eq
IMPLICIT NONE
REAL(SP), DIMENSION(:,,:), INTENT(IN) :: a
INTEGER(I4B), DIMENSION(:), INTENT(IN) :: indx
REAL(SP), DIMENSION(:), INTENT(INOUT) :: b
```

Solves the set of N linear equations $A \cdot X = B$. Here the $N \times N$ matrix a is input, not as the original matrix A , but rather as its LU decomposition, determined by the routine `ludcmp`. `indx` is input as the permutation vector of length N returned by `ludcmp`. b is input as the right-hand-side vector B , also of length N , and returns with the solution vector X . a and `indx` are not modified by this routine and can be left in place for successive calls with different right-hand sides b . This routine takes into account the possibility that b will begin with many zero elements, so it is efficient for use in matrix inversion.

```
INTEGER(I4B) :: i,n,ii,ll
```

```
REAL(SP) :: summ
```

```
n=assert_eq(size(a,1),size(a,2),size(indx),'lubksb')
```

```
ii=0
```

```

```
        ii=i
```

```
    end if
```

```
    b(i)=summ
```

```
end do
```

```
do i=n,1,-1
```

```
    b(i) = (b(i)-dot_product(a(i,i+1:n),b(i+1:n)))/a(i,i)
```

```
end do
```

```
END SUBROUTINE lubksb
```

When `ii` is set to a positive value, it will become the index of the first nonvanishing element of b . We now do the forward substitution, equation (2.3.6). The only new wrinkle is to unscramble the permutation as we go.

A nonzero element was encountered, so from now on we will have to do the dot product above.

Now we do the backsubstitution, equation (2.3.7).

Conceptually, the search for the first nonvanishing element of b (index `ii`) should be moved out of the first `do`-loop. However, in practice, the need to unscramble the permutation, and also considerations of performance

on scalar machines, cause us to write this very scalar-looking code. The performance penalty on parallel machines should be minimal.

* * *

Serial and parallel algorithms for tridiagonal problems are quite different. We therefore provide separate routines `tridag_ser` and `tridag_par`. In the MODULE `nr` interface file, one or the other of these (your choice) is given the generic name `tridag`. Of course, *either* version will work correctly on any computer; it is only a question of efficiency. See §22.2 for the numbering of the equation coefficients, and for a description of the parallel algorithm.

```

SUBROUTINE tridag_ser(a,b,c,r,u)
USE nrtype; USE nrutil, ONLY : assert_eq,nrerror

        -c(3:n-1:2)*u(4:n-2:2))/b(3:n-1:2)
      if (nm == n2) u(n)=(r(n)-a(n-1)*u(n-1))/b(n)
    end if
  END SUBROUTINE tridag_par

```

f90 The serial version `tridag_ser` is called when the routine has recursed its way down to sufficiently small subproblems. The point at which this occurs is determined by the parameter `NPAR_TRIDAG` whose optimal value is likely machine-dependent. Notice that `tridag_ser` must here be called by its specific name, not by the generic `tridag` (which might itself be overloaded with either `tridag_ser` or `tridag_par`).

★ ★ ★

```

SUBROUTINE banmul(a,m1,m2,x,b)
USE nrtype; USE nrutil, ONLY : assert_eq, arth
IMPLICIT NONE
REAL(SP), DIMENSION(:, :), INTENT(IN) :: a
INTEGER(I4B), INTENT(IN) :: m1, m2
REAL(SP), DIMENSION(:, :), INTENT(IN) :: x
REAL(SP), DIMENSION(:, :), INTENT(OUT) :: b

```

Matrix multiply $\mathbf{b} = \mathbf{A} \cdot \mathbf{x}$, where \mathbf{A} is band diagonal with $m1$ rows below the diagonal and $m2$ rows above. If the input vector \mathbf{x} and output vector \mathbf{b} are of length N , then the array $\mathbf{a}(1:N, 1:m1+m2+1)$ stores \mathbf{A} as follows: The diagonal elements are in $\mathbf{a}(1:N, m1+1)$. Subdiagonal elements are in $\mathbf{a}(j:N, 1:m1)$ (with $j > 1$ appropriate to the number of elements on each subdiagonal). Superdiagonal elements are in $\mathbf{a}(1:j, m1+2:m1+m2+1)$ with $j < N$ appropriate to the number of elements on each superdiagonal.

```

INTEGER(I4B) :: m_n
n=assert_eq(size(a,1),size(b),size(x),'banmul: n')
m=assert_eq(size(a,2),m1+m2+1,'banmul: m')
b=sum(a*eoshift(spread(x,dim=2,ncopies=m), &
  dim=1,shift=arth(-m1,1,m)),dim=2)
END SUBROUTINE banmul

```

f90

```

b=sum(a*eoshift(spread(x,dim=2,ncopies=m), &
  dim=1,shift=arth(-m1,1,m)),dim=2)

```

This is a good example of Fortran 90 at both its best and its worst: best, because it allows quite subtle combinations of fully parallel operations to be built up; worst, because the resulting code is virtually incomprehensible!

What is going on becomes clearer if we imagine a temporary array `y` with a declaration like `REAL(SP), DIMENSION(size(a,1),size(a,2)) :: y`. Then, the above single line decomposes into

```
y=spread(x,dim=2,ncopies=m)           [Duplicate x into columns of y.]
y=eoshift(y,dim=1,shift=arth(-m1,1,m)) [Shift columns by a linear progression.]
b=sum(a*y,dim=2)                       [Multiply by the band-diagonal elements,
                                       and sum.]
```

We use here a relatively rare subcase of the `eoshift` intrinsic, using a vector value for the `shift` argument to accomplish the simultaneous shifting of a bunch of columns, by different amounts (here specified by the linear progression returned by `arth`).

If you still don't see how this accomplishes the multiplication of a band diagonal matrix by a vector, work through a simple example by hand.

```
SUBROUTINE bandec(a,m1,m2,al,indx,d)
USE nrtype; USE nrutil, ONLY : assert_eq,imaxloc,swap,arth
IMPLICIT NONE
REAL(SP), DIMENSION(:,,:), INTENT(INOUT) :: a
INTEGER(I4B), INTENT(IN) :: m1,m2
REAL(SP), DIMENSION(:,,:), INTENT(OUT) :: al
INTEGER(I4B), DIMENSION(:), INTENT(OUT) :: indx
REAL(SP), INTENT(OUT) :: d
REAL(SP), PARAMETER :: TINY=1.0e-20_sp
```

Given an $N \times N$ band diagonal matrix **A** with `m1` subdiagonal rows and `m2` superdiagonal rows, compactly stored in the array `a(1:N,1:m1+m2+1)` as described in the comment for routine `banmul`, this routine constructs an *LU* decomposition of a rowwise permutation of **A**. The upper triangular matrix replaces `a`, while the lower triangular matrix is returned in `al(1:N,1:m1)`. `indx` is an output vector of length N that records the row permutation effected by the partial pivoting; `d` is output as ± 1 depending on whether the number of row interchanges was even or odd, respectively. This routine is used in combination with `banbks` to solve band-diagonal sets of equations.

```
INTEGER(I4B) :: i,k,l,m dum,mm,n
REAL(SP) :: dum
n=assert_eq(size(a,1),size(al,1),size(indx),'bandec: n')

  i=imaxloc(abs(a(k:l,1)))+k-1                             Find the pivot element.
  dum=a(i,1)
  if (dum == 0.0) a(k,1)=TINY
  Matrix is algorithmically singular, but proceed anyway with TINY pivot (desirable in some
  applications).
  indx(k)=i
  if (i /= k) then                                           Interchange rows.
    d=-d
    call swap(a(k,1:mm),a(i,1:mm))
  end if
  do i=k+1,l                                                 Do the elimination.
    dum=a(i,1)/a(k,1)
    al(k,i-k)=dum
    a(i,1:mm-1)=a(i,2:mm)-dum*a(k,2:mm)
    a(i,mm)=0.0
  end do
end do
END SUBROUTINE bandec
```

`a(1:m1,:)=eoshift(a(1:m1,:),...)` See similar discussion of `eoshift` for `banmul`, just above.

`i=imaxloc(abs(a(k:1,1)))+k-1` See discussion of `imaxloc` on p. 1017.

Notice that the above is *not* well parallelized for MMP machines: the outer do-loop is done N times, where N , the diagonal length, is potentially the largest dimension in the problem. Small-scale parallel (SSP) machines, and scalar machines, are not disadvantaged, because the parallelism of order $mm=m1+m2+1$ in the inner loops can be enough to saturate their concurrency.

We don't know of an N -parallel algorithm for decomposing band diagonal matrices, at least one that has any reasonably concise expression in Fortran 90. Conceptually, one can view a band diagonal matrix as a *block tridiagonal* matrix, and then apply the same recursive strategy as was used in `tridag-par`. However, the implementation details of this are daunting. (We would welcome a user-contributed routine, clear, concise, and with parallelism of order N .)

```
SUBROUTINE banbks(a,m1,m2,al,indx,b)
USE nrtype; USE nrutil, ONLY : assert_eq,swap
IMPLICIT NONE
REAL(SP), DIMENSION(:,:), INTENT(IN) :: a,al
INTEGER(I4B), INTENT(IN) :: m1,m2
INTEGER(I4B), DIMENSION(:), INTENT(IN) :: indx
REAL(SP), DIMENSION(:), INTENT(INOUT) :: b
    Given the arrays a, al, and indx as returned from bandec, and given a right-hand-side
    vector b, solves the band diagonal linear equations  $A \cdot x = b$ . The solution vector  $x$  overwrites
    b. The other input arrays are not modified, and can be left in place for successive calls with
    different right-hand sides.
    INTEGER(I4B) :: i,k,l,mdum,mm,n
    n=assert_eq(size(a,1),size(al,1),size(b),size(indx),'banbks: n')
    mm=assert_eq(size(a,2),m1+m2+1,'banbks: mm')
    mdum=assert_eq(size(al,2),m1,'banbks: mdum')
    do k=1,n
        Forward substitution, unscrambling the permuted rows as we
        l=min(n,m1+k)
        i=indx(k)
        if (i /= k) call swap(b(i),b(k))
        b(k+1:l)=b(k+1:l)-al(k,1:l-k)*b(k)
    end do
    do i=n,1,-1
        Backsubstitution.
        l=min(mm,n-i+1)
        b(i)=(b(i)-dot_product(a(i,2:l),b(1+i:i+1-1)))/a(i,1)
    end do
END SUBROUTINE banbks
```

As for `bandec`, the routine `banbks` is not parallelized on the large dimension N , though it does give the compiler the opportunity for ample small-scale parallelization inside the loops.

```

SUBROUTINE mprove(a,alud,indx,b,x)
USE nrtype; USE nrutil, ONLY : assert_eq
USE nr, ONLY : lubksb
IMPLICIT NONE
REAL(SP), DIMENSION(:,:), INTENT(IN) :: a,alud
INTEGER(I4B), DIMENSION(:), INTENT(IN) :: indx
REAL(SP), DIMENSION(:), INTENT(IN) :: b
REAL(SP), DIMENSION(:), INTENT(OUT) :: x
    Improves a solution vector x of the linear set of equations  $A \cdot X = B$ . The  $N \times N$  matrix a
    and the  $N$ -dimensional vectors b and x are input. Also input is alud, the  $LU$  decomposition
    of a as returned by ludcmp, and the  $N$ -dimensional vector indx also returned by that
    routine. On output, only x is modified, to an improved set of values.
INTEGER(I4B) :: ndum
REAL(SP), DIMENSION(size(a,1)) :: r
ndum=assert_eq((/size(a,1),size(a,2),size(alud,1),size(alud,2),size(b),&
    size(x),size(indx)/),'mprove')
r=matmul(real(a,dp),real(x,dp))-real(b,dp)
    Calculate the right-hand side, accumulating the residual in double precision.
call lubksb(alud,indx,r)          Solve for the error term,
x=x-r                             and subtract it from the old solution.
END SUBROUTINE mprove

```

F90 `assert_eq((/.../),'mprove')` This overloaded version of the `nrutil` routine `assert_eq` makes use of a trick for passing a variable number of scalar arguments to a routine: Put them into an array constructor, `(/.../)`, and pass the array. The receiving routine can use the `size` intrinsic to count them. The technique has some obvious limitations: All the arguments in the array must be of the same type; and the arguments are passed, in effect, by *value*, not by address, so they must be, in effect, `INTENT(IN)`.

`r=matmul(real(a,dp),real(x,dp))-real(b,dp)` Since Fortran 90's elemental intrinsics operate with the type of their arguments, we can use the `real(...,dp)`'s to force the `matmul` matrix multiplication to be done in double precision, which is what we want. In Fortran 77, we would have to do the matrix multiplication with temporary double precision variables, both inconvenient and (since Fortran 77 has no dynamic memory allocation) a waste of memory.

★ ★ ★

```

SUBROUTINE svbksb_sp(u,w,v,b,x)
USE nrtype; USE nrutil, ONLY : assert_eq
REAL(SP), DIMENSION(:,:), INTENT(IN) :: u,v
REAL(SP), DIMENSION(:), INTENT(IN) :: w,b
REAL(SP), DIMENSION(:), INTENT(OUT) :: x
    Solves  $A \cdot X = B$  for a vector  $X$ , where  $A$  is specified by the arrays u, v, w as returned
    by svdcmp. Here u is  $M \times N$ , v is  $N \times N$ , and w is of length  $N$ . b is the  $M$ -dimensional
    input right-hand side. x is the  $N$ -dimensional output solution vector. No input quantities
    are destroyed, so the routine may be called sequentially with different b's.
INTEGER(I4B) :: mdum,ndum
REAL(SP), DIMENSION(size(x)) :: tmp
mdum=assert_eq(size(u,1),size(b),'svbksb_sp: mdum')
ndum=assert_eq((/size(u,2),size(v,1),size(v,2),size(w),size(x)/),&
    'svbksb_sp: ndum')
where (w /= 0.0)
    tmp=matmul(b,u)/w          Calculate  $\text{diag}(1/w_j)U^T B$ ,
elsewhere
    tmp=0.0                    but replace  $1/w_j$  by zero if  $w_j = 0$ .
end where

```

```
x=matmul(v,tmp)           Matrix multiply by V to get answer.
END SUBROUTINE svbksb_sp
```

f90 where (w /= 0.0)...tmp=...elsewhere...tmp= Normally, when a where ...elsewhere construction is used to set a variable (here tmp) to one or another value, we like to replace it with a merge expression. Here, however, the where is required to guarantee that a division by zero doesn't occur. The rule is that where will *never* evaluate expressions that are excluded by the mask in the where line, but other constructions, like merge, *might* perform speculative evaluation of more than one possible outcome before selecting the applicable one.

Because singular value decomposition is something that one often wants to do in double precision, we include a double-precision version. In nr, the single- and double-precision versions are overloaded onto the name svbksb.

```

The SVD algorithm implemented above does not parallelize very well. There are two parts to the algorithm. The first, reduction to bidiagonal form, can be parallelized. The second, the iterative diagonalization of the bidiagonal form, uses QR transformations that are intrinsically serial. There have been proposals for parallel SVD algorithms [2], but we do not have sufficient experience with them yet to recommend them over the well-established serial algorithm.

tempm(1:n)=matmul...a(i:m,1:n)=...outerprod... Here is an example of an update as in equation (22.1.6). In this case b_i is independent of i : It is simply $1/h$. The lines beginning tempm(1:m)=matmul about 16 lines down are of a similar form, but with the terms in the opposite order in the matmul.

As with svbksb, single- and double-precision versions of the routines are overloaded onto the name svdcmp in nr.

SUBROUTINE cyclic(a,b,c,alpha,beta,r,x)
USE nrtype; USE nrutil, ONLY : assert,assert_eq
USE nr, ONLY : tridag
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN):: a,b,c,r
REAL(SP), INTENT(IN) :: alpha,beta
REAL(SP), DIMENSION(:), INTENT(OUT):: x
  Solves the "cyclic" set of linear equations given by equation (2.7.9). a, b, c, and r are
  input vectors, while x is the output solution vector, all of the same size. alpha and beta
  are the corner entries in the matrix. The input is not modified.
INTEGER(I4B) :: n
REAL(SP) :: fact,gamma
REAL(SP), DIMENSION(size(x)) :: bb,u,z
n=assert_eq(/size(a),size(b),size(c),size(r),size(x)/),'cyclic')
call assert(n > 2, 'cyclic arg')
gamma=-b(1)
bb(1)=b(1)-gamma
bb(n)=b(n)-alpha*beta/gamma
bb(2:n-1)=b(2:n-1)
call tridag(a(2:n),bb,c(1:n-1),r,x)
u(1)=gamma
u(n)=alpha
u(2:n-1)=0.0
call tridag(a(2:n),bb,c(1:n-1),u,z)
fact=(x(1)+beta*x(n)/gamma)/(1.0_sp+z(1)+beta*z(n)/gamma)
x=x-fact*z
END SUBROUTINE cyclic

```

Avoid subtraction error in forming bb(1).
Set up the diagonal of the modified tridiagonal system.

Solve $\mathbf{A} \cdot \mathbf{x} = \mathbf{r}$.
Set up the vector \mathbf{u} .

Solve $\mathbf{A} \cdot \mathbf{z} = \mathbf{u}$.
Form $\mathbf{v} \cdot \mathbf{x} / (1 + \mathbf{v} \cdot \mathbf{z})$.
Now get the solution vector \mathbf{x} .

The parallelism in cyclic is in tridag. Users with multiprocessor machines will want to be sure that, in nrutil, they have set the name tridag to be overloaded with tridag_par instead of tridag_ser.

* * *

The routines sprsin, sprsax, sprstx, sprstp, and sprsdiag give roughly equivalent functionality to the corresponding Fortran 77 routines, but they are *not* plug compatible. Instead, they take advantage of (and illustrate) several Fortran 90 features that are not present in Fortran 77.

In the module nrtype we define a TYPE sprs2_sp for two-dimensional sparse, square, matrices, in single precision, as follows

```

TYPE sprs2_sp
  INTEGER(I4B) :: n,len
  REAL(SP), DIMENSION(:), POINTER :: val
  INTEGER(I4B), DIMENSION(:), POINTER :: irow
  INTEGER(I4B), DIMENSION(:), POINTER :: jcol
END TYPE sprs2_sp

```

This has much less structure to it than the "row-indexed sparse storage mode" used in Volume 1. Here, a sparse matrix is just a list of values, and corresponding lists giving the row and column number that each value is in. Two integers n and len give, respectively, the underlying size (number of rows or columns) in the full matrix, and the number of stored nonzero values. While the previously used row-indexed scheme can be somewhat more efficient for serial machines, it does not parallelize conveniently, while this one does (though with some caveats; see below).

```

SUBROUTINE sprsin_sp(a,thresh,sa)
USE nrtype; USE nrutil, ONLY : arth,assert_eq
IMPLICIT NONE
REAL(SP), DIMENSION(:,,:), INTENT(IN) :: a
REAL(SP), INTENT(IN) :: thresh
TYPE(sprs2_sp), INTENT(OUT) :: sa
    Converts a square matrix a to sparse storage format as sa. Only elements of a with mag-
    nitude  $\geq$  thresh are retained.
INTEGER(I4B) :: n,len
LOGICAL(LGT), DIMENSION(size(a,1),size(a,2)) :: mask
n=assert_eq(size(a,1),size(a,2),'sprsin_sp')
mask=abs(a)>thresh
len=count(mask)          How many elements to store?
allocate(sa%val(len),sa%irow(len),sa%jcol(len))
sa%n=n
sa%len=len
sa%val=pack(a,mask)       Grab the values, row, and column numbers.
sa%irow=pack(spread(arth(1,1,n),2,n),mask)
sa%jcol=pack(spread(arth(1,1,n),1,n),mask)
END SUBROUTINE sprsin_sp

```

```

SUBROUTINE sprsin_dp(a,thresh,sa)
USE nrtype; USE nrutil, ONLY : arth,assert_eq
IMPLICIT NONE
REAL(DP), DIMENSION(:,,:), INTENT(IN) :: a
REAL(DP), INTENT(IN) :: thresh
TYPE(sprs2_dp), INTENT(OUT) :: sa
INTEGER(I4B) :: n,len
LOGICAL(LGT), DIMENSION(size(a,1),size(a,2)) :: mask
n=assert_eq(size(a,1),size(a,2),'sprsin_dp')
mask=abs(a)>thresh
len=count(mask)
allocate(sa%val(len),sa%irow(len),sa%jcol(len))
sa%n=n
sa%len=len
sa%val=pack(a,mask)
sa%irow=pack(spread(arth(1,1,n),2,n),mask)
sa%jcol=pack(spread(arth(1,1,n),1,n),mask)
END SUBROUTINE sprsin_dp

```

Note that the routines `sprsin_sp` and `sprsin_dp` — single and double precision versions of the same algorithm — are overloaded onto the name `sprsin` in module `nr`. We supply both forms because the routine `linbcg`, below, works in double precision.

`sa%irow=pack(spread(arth(1,1,n),2,n),mask)` The trick here is to use the same `mask`, `abs(a)>thresh`, in three consecutive `pack` expressions, thus guaranteeing that the corresponding elements of the array argument get selected for packing. The first time, we get the desired matrix element values. The second time (above code fragment), we construct a matrix with each element having the value of its *row* number. The third time, we construct a matrix with each element having the value of its *column* number.

```

SUBROUTINE sprsax_sp(sa,x,b)
USE nrtype; USE nrutil, ONLY : assert_eq,scatter_add
IMPLICIT NONE
TYPE(sprs2_sp), INTENT(IN) :: sa
REAL(SP), DIMENSION (:), INTENT(IN) :: x
REAL(SP), DIMENSION (:), INTENT(OUT) :: b
    Multiply a matrix sa in sparse matrix format by a vector x, giving a vector b.
INTEGER(I4B) :: ndum
ndum=assert_eq(sa%n,size(x),size(b),'sprsax_sp')
b=0.0_sp
call scatter_add(b,sa%val*x(sa%jcol),sa%irow)
    Each sparse matrix entry adds a term to some component of b.
END SUBROUTINE sprsax_sp

```

```

SUBROUTINE sprsax_dp(sa,x,b)
USE nrtype; USE nrutil, ONLY : assert_eq,scatter_add
IMPLICIT NONE
TYPE(sprs2_dp), INTENT(IN) :: sa
REAL(DP), DIMENSION (:), INTENT(IN) :: x
REAL(DP), DIMENSION (:), INTENT(OUT) :: b
INTEGER(I4B) :: ndum
ndum=assert_eq(sa%n,size(x),size(b),'sprsax_dp')
b=0.0_dp
call scatter_add(b,sa%val*x(sa%jcol),sa%irow)
END SUBROUTINE sprsax_dp

```

call scatter_add(b,sa%val*x(sa%jcol),sa%irow) Since more than one component of the middle vector argument will, in general, need to be added into the same component of b, we must resort to a call to the nrutil routine scatter_add to achieve parallelism. *However*, this parallelism is achieved only if a parallel version of scatter_add is available! As we have discussed previously (p. 984), Fortran 90 does not provide any scatter-with-combine (here, scatter-with-add) facility, insisting instead that indexed operations yield non-colliding addresses. Luckily, almost all parallel machines do provide such a facility as a library program. In HPF, for example, the equivalent of scatter_add is SUM_SCATTER.

The call to scatter_add above is equivalent to the do-loop

```

b=0.0
do k=1,sa%len
    b(sa%irow(k))=b(sa%irow(k))+sa%val(k)*x(sa%jcol(k))
end do

```

```

SUBROUTINE sprstx_sp(sa,x,b)
USE nrtype; USE nrutil, ONLY : assert_eq,scatter_add
IMPLICIT NONE
TYPE(sprs2_sp), INTENT(IN) :: sa
REAL(SP), DIMENSION (:), INTENT(IN) :: x
REAL(SP), DIMENSION (:), INTENT(OUT) :: b
    Multiply the transpose of a matrix sa in sparse matrix format by a vector x, giving a vector b.
INTEGER(I4B) :: ndum
ndum=assert_eq(sa%n,size(x),size(b),'sprstx_sp')
b=0.0_sp
call scatter_add(b,sa%val*x(sa%irow),sa%jcol)
    Each sparse matrix entry adds a term to some component of b.
END SUBROUTINE sprstx_sp

```

```

SUBROUTINE sprstx_dp(sa,x,b)
USE nrtype; USE nrutil, ONLY : assert_eq,scatter_add
IMPLICIT NONE
TYPE(sprs2_dp), INTENT(IN) :: sa
REAL(DP), DIMENSION (:), INTENT(IN) :: x
REAL(DP), DIMENSION (:), INTENT(OUT) :: b
INTEGER(I4B) :: ndum
ndum=assert_eq(sa%n,size(x),size(b),'sprstx_dp')
b=0.0_dp
call scatter_add(b,sa%val*x(sa%irow),sa%jcol)
END SUBROUTINE sprstx_dp

```

Precisely the same comments as for sprsax apply to sprstx. The call to scatter_add is here equivalent to

```

b=0.0
do k=1,sa%len
    b(sa%jcol(k))=b(sa%jcol(k))+sa%val(k)*x(sa%irow(k))
end do

```

```

SUBROUTINE sprstp(sa)
USE nrtype
IMPLICIT NONE
TYPE(sprs2_sp), INTENT(INOUT) :: sa

i(1:k)=pack(sa%irow(1:l),mask)    ...and their locations.
deallocate(mask)
b=0.0
b(i(1:k))=val(1:k)    Zero b because zero values not stored in sa.
                        Scatter values into correct slots.
END SUBROUTINE sprsdiag_sp

```

```

SUBROUTINE sprsdiag_dp(sa,b)
USE nrtype; USE nrutil, ONLY : array_copy,assert_eq
IMPLICIT NONE
TYPE(sprs2_dp), INTENT(IN) :: sa
REAL(DP), DIMENSION(:), INTENT(OUT) :: b
REAL(DP), DIMENSION(size(b)) :: val
INTEGER(I4B) :: k,l,ndum,nerr
INTEGER(I4B), DIMENSION(size(b)) :: i
LOGICAL(LGT), DIMENSION(:), ALLOCATABLE :: mask
ndum=assert_eq(sa%n,size(b),'sprsdiag_dp')
l=sa%len
allocate(mask(l))
mask = (sa%irow(1:l) == sa%jcol(1:l))
call array_copy(pack(sa%val(1:l),mask),val,k,nerr)
i(1:k)=pack(sa%irow(1:l),mask)
deallocate(mask)
b=0.0
b(i(1:k))=val(1:k)
END SUBROUTINE sprsdiag_dp

```

f90 call array_copy(pack(sa%val(1:l),mask),val,k,nerr) We use the nrutil routine array_copy because we don't know in advance how many nonzero diagonal elements will be selected by mask. Of course we could count them with a count(mask), but this is an extra step, and inefficient on scalar machines.

i(1:k)=pack(sa%irow(1:l),mask) Using the same mask, we pick out the corresponding locations of the diagonal elements. No need to use array_copy now, since we know the value of k.

b(i(1:k))=val(1:k) Finally, we can put each element in the right place. Notice that if the sparse matrix is ill-formed, with more than one value stored for the same diagonal element (which should not happen!) then the vector subscript i(1:k) is a "many-one section" and its use on the left-hand side is illegal.

* * *

```

SUBROUTINE linbcg(b,x,itol,tol,itmax,iter,err)
USE nrtype; USE nrutil, ONLY : assert_eq,nrerror
USE nr, ONLY : atimes,asolve,snrnm
IMPLICIT NONE
REAL(DP), DIMENSION(:), INTENT(IN) :: b      Double precision is a good idea in this
REAL(DP), DIMENSION(:), INTENT(INOUT) :: x    routine.
INTEGER(I4B), INTENT(IN) :: itol,itmax
REAL(DP), INTENT(IN) :: tol
INTEGER(I4B), INTENT(OUT) :: iter
REAL(DP), INTENT(OUT) :: err
REAL(DP), PARAMETER :: EPS=1.0e-14_dp

```

Solves $A \cdot x = b$ for x , given b of the same length, by the iterative biconjugate gradient method. On input x should be set to an initial guess of the solution (or all zeros); $itol$ is 1,2,3, or 4, specifying which convergence test is applied (see text); $itmax$ is the maximum number of allowed iterations; and tol is the desired convergence tolerance. On output, x is reset to the improved solution, $iter$ is the number of iterations actually taken, and err is the estimated error. The matrix A is referenced only through the user-supplied routines $atimes$, which computes the product of either A or its transpose on a vector; and $asolve$,

which solves $\tilde{\mathbf{A}} \cdot \mathbf{x} = \mathbf{b}$ or $\tilde{\mathbf{A}}^T \cdot \mathbf{x} = \mathbf{b}$ for some preconditioner matrix $\tilde{\mathbf{A}}$ (possibly the trivial diagonal part of \mathbf{A}).

FUNCTION splint(xa,ya,y2a,x)
USE nrtype; USE nrutil, ONLY : assert_eq,nrerror
USE nr, ONLY: locate
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: xa,ya,y2a
REAL(SP), INTENT(IN) :: x
REAL(SP) :: splint

```

Given the arrays *xa* and *ya*, which tabulate a function (with the *xa*_{*i*}'s in increasing or decreasing order), and given the array *y2a*, which is the output from *spline* above, and given a value of *x*, this routine returns a cubic-spline interpolated value. The arrays *xa*, *ya* and *y2a* are all of the same size.

```

INTEGER(I4B) :: khi,klo,n
REAL(SP) :: a,b,h
n=assert_eq(size(xa),size(ya),size(y2a),'splint')
klo=max(min(locate(xa,x),n-1),1)

```

We will find the right place in the table by means of *locate*'s bisection algorithm. This is optimal if sequential calls to this routine are at random values of *x*. If sequential calls are in order, and closely spaced, one would do better to store previous values of *klo* and *khi* and test if they remain appropriate on the next call.

```

khi=klo+1
h=xa(khi)-xa(klo)
if (h == 0.0) call nrerror('bad xa input in splint')
a=(xa(khi)-x)/h
b=(x-xa(klo))/h
splint=a*ya(klo)+b*ya(khi)+((a**3-a)*y2a(klo)+(b**3-b)*y2a(khi))*(h**2)/6.0_sp
END FUNCTION splint

```

klo and *khi* now bracket the input value of *x*. The *xa*'s must be distinct. Cubic spline polynomial is now evaluated.

f90 *klo*=max(min(*locate*(*xa*,*x*),*n*-1),1) In the Fortran 77 version of *splint*, there is in-line code to find the location in the table by bisection. Here we prefer an explicit call to *locate*, which performs the bisection. On some massively multiprocessor (MMP) machines, one might substitute a different, more parallel algorithm (see next note).

else
  locate=jl
end if
END FUNCTION locate

```

The use of bisection is perhaps a sin on a genuinely parallel machine, but (since the process takes only logarithmically many sequential steps) it is at most a *small* sin. One can imagine a “fully parallel” implementation like,

```

k=iminloc(abs(x-xx))
if ((x < xx(k)) .eqv. (xx(1) < xx(n))) then
  locate=k-1
else
  locate=k
end if

```

Problem is, unless the number of *physical* (not logical) processors participating in the `iminloc` is larger than N , the length of the array, this “parallel” code turns a $\log N$ algorithm into one scaling as N , quite an unacceptable inefficiency. So we prefer to be small sinners and `bisect`.

```

SUBROUTINE hunt(xx,x,jlo)
USE nrtype
IMPLICIT NONE
INTEGER(I4B), INTENT(INOUT) :: jlo
REAL(SP), INTENT(IN) :: x
REAL(SP), DIMENSION(:), INTENT(IN) :: xx
  Given an array xx(1:N), and given a value x, returns a value jlo such that x is between
  xx(jlo) and xx(jlo+1). xx must be monotonic, either increasing or decreasing. jlo = 0
  or jlo = N is returned to indicate that x is out of range. jlo on input is taken as the
  initial guess for jlo on output.

  a(:,k)=-(s(k)-a(:,k-1))/x(:)
end do
s=y/polcoe
polcoe=matmul(s,a)          Solve linear system.
END FUNCTION polcoe
```

For a description of the coding here, see §22.3, especially equation (22.3.9). You might also want to compare the coding here with the Fortran 77 version, and also look at the description of the method on p. 84 in Volume 1. The Fortran 90 implementation here is in fact much closer to that description than is the Fortran 77 method, which goes through some acrobatics to roll the synthetic division and matrix multiplication into a single set of two nested loops. The price we pay, here, is storage for the matrix a . Since the degree of any useful polynomial is not a very large number, this is essentially no penalty.

Also worth noting is the way that parallelism is brought to the required synthetic division. For a *single* such synthetic division (e.g., as accomplished by the `nrutil` routine `poly_term`), parallelism can be obtained only by recursion. Here things are much simpler, because we need a whole bunch of simultaneous and independent synthetic divisions; so we can just do them in the obvious, data-parallel, way.

Pack a temporary vector x.
Matrix multiply by the stored table.
Unpack the result into the output table.

f90 `x=matmul(wt,x) ... c=reshape(x,(/4,4/),order=(/2,1/))` It is a powerful technique to combine the `matmul` intrinsic with `reshape`'s of the input or output. The idea is to use `matmul` whenever the calculation can be cast into the form of a linear mapping between input and output objects. Here the `order=(/2,1/)` parameter specifies that we want the packing to be by rows, not by Fortran's default of columns. (In this two-dimensional case, it's the equivalent of applying transpose.)

Chapter B4. Integration of Functions

```

SUBROUTINE trapzd(func,a,b,s,n)
USE nrtype; USE nrutil, ONLY : arth
IMPLICIT NONE
REAL(SP), INTENT(IN) :: a,b
REAL(SP), INTENT(OUT) :: s
INTEGER(I4B), INTENT(IN) :: n
INTERFACE
    FUNCTION func(x)
        USE nrtype
        REAL(SP), DIMENSION(:), INTENT(IN) :: x
        REAL(SP), DIMENSION(size(x)) :: func
    END FUNCTION func
END INTERFACE

```

END INTERFACE

This routine computes the n th stage of refinement of an extended trapezoidal rule. `func` is input as the name of the function to be integrated between limits a and b , also input. When called with $n=1$, the routine returns as s the crudest estimate of $\int_a^b f(x)dx$. Subsequent calls with $n=2,3,\dots$ (in that sequential order) will improve the accuracy of s by adding 2^{n-2} additional interior points. s should not be modified between sequential calls.

```

REAL(SP) :: del,fsum
INTEGER(I4B) :: it
if (n == 1) then
    s=0.5_sp*(b-a)*sum(func( (/ a,b /) ))
else
    it=2**(n-2)
    del=(b-a)/it
    fsum=sum(func(arth(a+0.5_sp*del,del,it)))
    s=0.5_sp*(s+del*fsum)
end if
END SUBROUTINE trapzd

```

This is the spacing of the points to be added.

This replaces s by its refined value.

f90 While most of the quadrature routines in this chapter are coded as functions, `trapzd` is a subroutine because the argument s that returns the function value must also be supplied as an input parameter. We could change the subroutine into a function by declaring s to be a local variable with the `SAVE` attribute. However, this would prevent us from being able to use the routine recursively to do multidimensional quadrature (see `quad3d` on p. 1065). When s is left as an argument, a fresh copy is created on each recursive call. As a `SAVE'd` variable, by contrast, its value would get overwritten on each call, and the code would not be properly “re-entrant.”

`s=0.5_sp*(b-a)*sum(func((/ a,b /)))` Note how we use the `(/.../)` construct to supply a set of scalar arguments to a vector function.

```

```

END INTERFACE
INTEGER(I4B), PARAMETER :: JMAX=20,JMAXP=JMAX+1,K=5,KM=K-1
REAL(SP), PARAMETER :: EPS=1.0e-6_sp

```

Returns the integral of the function `func` from `a` to `b`. Integration is performed by Romberg's method of order $2K$, where, e.g., $K=2$ is Simpson's rule.

Parameters: `EPS` is the fractional accuracy desired, as determined by the extrapolation error estimate; `JMAX` limits the total number of steps; `K` is the number of points used in the extrapolation.

```

REAL(SP), DIMENSION(JMAXP) :: h,s
REAL(SP) :: dqromb
INTEGER(I4B) :: j
h(1)=1.0

```

These store the successive trapezoidal approximations and their relative stepsizes.

```

do j=1,JMAX
  call trapzd(func,a,b,s(j),j)
  if (j >= K) then
    call polint(h(j-KM:j),s(j-KM:j),0.0_sp,qromb,dqromb)
    if (abs(dqromb) <= EPS*abs(qromb)) RETURN
  end if
  s(j+1)=s(j)
  h(j+1)=0.25_sp*h(j)
end do
call nrerror('qromb: too many steps')
END FUNCTION qromb

```

This is a key step: The factor is 0.25 even though the stepsize is decreased by only 0.5. This makes the extrapolation a polynomial in h^2 as allowed by equation (4.2.1), not just a polynomial in h .

```

This routine computes the n th stage of refinement of an extended midpoint rule. `func` is input as the name of the function to be integrated between limits `a` and `b`, also input. When

called with $n=1$, the routine returns as s the crudest estimate of $\int_a^b f(x)dx$. Subsequent calls with $n=2,3,\dots$ (in that sequential order) will improve the accuracy of s by adding $(2/3) \times 3^{n-1}$ additional interior points. s should not be modified between sequential calls.

```

REAL(SP) :: del
INTEGER(I4B) :: it
REAL(SP), DIMENSION(2*3**(n-2)) :: x
if (n == 1) then
    s=(b-a)*sum(func( (/0.5_sp*(a+b)/) ))
else
    it=3**(n-2)
    del=(b-a)/(3.0_sp*it)
    x(1:2*it-1:2)=arth(a+0.5_sp*del,3.0_sp*del,it)
    x(2:2*it:2)=x(1:2*it-1:2)+2.0_sp*del
    s=s/3.0_sp*del*sum(func(x))
end if
END SUBROUTINE midpnt

```

The added points alternate in spacing between del and $2*del$.
The new sum is combined with the old integral to give a refined integral.

$midpnt$ is a subroutine and not a function for the same reasons as $trapzd$.

This is also true for the other $mid\dots$ routines below.

$s=(b-a)*sum(func((/0.5_sp*(a+b)/)))$ Here we use $(/\dots/)$ to pass a single scalar argument to a vector function.

REAL(SP), PARAMETER :: EPS=1.0e-6

```

Romberg integration on an open interval. Returns the integral of the function $func$ from a to b , using any specified integrating subroutine $choose$ and Romberg's method. Normally $choose$ will be an open formula, not evaluating the function at the endpoints. It is assumed that $choose$ triples the number of steps on each call, and that its error series contains only

even powers of the number of steps. The routines `midpnt`, `midinf`, `midsql`, `midsqu`, and `midexp` are possible choices for choose. The parameters have the same meaning as in `qromb`.

```

REAL(SP), DIMENSION(JMAXP) :: h,s
REAL(SP) :: dqromo
INTEGER(I4B) :: j
h(1)=1.0
do j=1,JMAX
  call choose(func,a,b,s(j),j)
  if (j >= K) then
    call polint(h(j-KM:j),s(j-KM:j),0.0_sp,qromo,dqromo)
    if (abs(dqromo) <= EPS*abs(qromo)) RETURN
  end if
  s(j+1)=s(j)
  h(j+1)=h(j)/9.0_sp
end do
call nrerror('qromo: too many steps')
END FUNCTION qromo

```

This is where the assumption of step tripling and an even error series is used.

```

The roots are symmetric in the interval, so we only have to find half of them.

Initial approximations to the roots.

Newton's method carried out simultaneously on the roots.

Loop up the recurrence relation to get the Legendre polynomials evaluated at z.

Newton's method.

Often we have an iterative procedure that has to be applied until all components of a vector have satisfied a convergence criterion. Some components of the vector might converge sooner than others, and it is inefficient on a small-scale parallel (SSP) machine to continue iterating on those components. The general structure we use for such an iteration is exemplified by the following lines from `gauleg`:

```

LOGICAL(LGT), DIMENSION((size(x)+1)/2) :: unfinished
...
unfinished=.true.
do its=1,MAXIT

```

```

      where (unfinished)
      ...
      unfinished=(abs(z-z1) > EPS)
    end where
    if (.not. any(unfinished)) exit
  end do
  if (its == MAXIT+1) call nrerror('too many iterations in gauleg')

```

We use the logical mask `unfinished` to control which vector components are processed inside the `where`. The mask gets updated on each iteration by testing whether any further vector components have converged. When all have converged, we exit the iteration loop. Finally, we check the value of `its` to see whether the maximum allowed number of iterations was exceeded before all components converged.

The logical expression controlling the `where` block (in this case `unfinished`) gets evaluated completely on entry into the `where`, and it is then perfectly fine to modify it inside the block. The modification affects only the *next* execution of the `where`.

On a strictly *serial* machine, there is of course some penalty associated with the above scheme: after a vector component converges, its corresponding component in `unfinished` is redundantly tested on each further iteration, until the slowest-converging component is done. If the number of iterations required does not vary too greatly from component to component, this is a minor, often negligible, penalty. However, one should be on the alert against algorithms whose worst-case convergence could differ from typical convergence by orders of magnitude. For these, one would need to implement a more complicated packing-unpacking scheme. (See discussion in Chapter B6, especially introduction, p. 1083, and notes for `factr1`, p. 1087.)

  END SUBROUTINE gaulag

```

The key difficulty in parallelizing this routine starting from the Fortran 77 version is that the initial guesses for the roots of the Laguerre polynomials were given in terms of previously determined roots. This prevents one from finding all the roots simultaneously. The solution is to come up with a new approximation to the roots that is a simple explicit formula, like the formula we used for the Legendre roots in `gauleg`.

We start with the approximation to $L_n^\alpha(x)$ given in equation (10.15.8) of [1]. We keep only the first term and ask when it is zero. This gives the following prescription for the k th root x_k of $L_n^\alpha(x)$: Solve for θ the equation

$$2\theta - \sin 2\theta = \frac{4n - 4k + 3}{4n + 2\alpha + 2} \pi \quad (\text{B4.1})$$

Since $1 \leq k \leq n$ and $\alpha > -1$, we can always find a value such that $0 < \theta < \pi/2$. Then the approximation to the root is

$$x_k = (4n + 2\alpha + 2) \cos^2 \theta \quad (\text{B4.2})$$

This typically gives 3-digit accuracy, more than enough for the Newton iteration to be able to refine the root. Unfortunately equation (B4.1) is not an explicit formula for θ . (You may recognize it as being of the same form as Kepler's equation in mechanics.) If we call the right-hand side of (B4.1) y , then we can get an explicit formula by working out the power series for $y^{1/3}$ near $\theta = 0$ (using a computer algebra program). Next invert the series to give θ as a function of $y^{1/3}$. Finally, economize the series (see §5.11). The result is the concise approximation

$$\theta = 0.9084064y^{1/3} + 5.214976 \times 10^{-2}y + 2.579930 \times 10^{-3}y^{5/3} + 3.986126 \times 10^{-3}y^{7/3} \quad (\text{B4.3})$$

```

  w(n-m+1:-1)=w(1:m)
END SUBROUTINE gauher

```

The roots are symmetric about the origin, so we have to find only half of them.

Initial approximations to the roots.

Newton's method carried out simultaneously on the roots.

Loop up the recurrence relation to get the Hermite polynomials evaluated at z.

Newton's formula.

Store the root and its symmetric counterpart.

Compute the weight and its symmetric counterpart.

Once again we need an explicit approximation for the polynomial roots, this time for $H_n(x)$. We can use the same approximation scheme as for $L_n^\alpha(x)$, since

$$H_{2m}(x) \propto L_m^{-1/2}(x^2), \quad H_{2m+1}(x) \propto x L_m^{1/2}(x^2) \quad (\text{B4.4})$$

Equations (B4.1) and (B4.2) become

$$2\theta - \sin 2\theta = \frac{4k-1}{2n+1}\pi$$

$$x_k = \sqrt{2n+1} \cos \theta$$
(B4.5)

Here $k = 1, 2, \dots, m$ where $m = [(n+1)/2]$, and $k = 1$ is the largest root. The negative roots follow from symmetry. The root at $x = 0$ for odd n is included in this approximation.

```

      gammln(n+alf+bet+1.0_sp))*temp*2.0_sp**alfbet/(pp*p2)
END SUBROUTINE gaujac
```

Now we need an explicit approximation for the roots of the Jacobi polynomials $P_n^{(\alpha,\beta)}(x)$. We start with the asymptotic expansion (10.14.10) of [1]. Setting this to zero gives the formula

$$x = \cos \left[\frac{k - 1/4 + \alpha/2}{n + (\alpha + \beta + 1)/2} \pi \right] \quad (\text{B4.6})$$

This is better than the formula (22.16.1) in [2], especially at small and moderate n .

* * *

As discussed in Volume 1, multidimensional quadrature can be performed by calling a one-dimensional quadrature routine along each dimension.

If the same routine is used for all such calls, then the calls are recursive. The file `quad3d.f90` contains two modules, `quad3d_qgaus_mod` and `quad3d_qromb_mod`. In the first, the basic one-dimensional quadrature routine is a 10-point Gaussian quadrature routine called `qgaus` and three-dimensional quadrature is performed by calling `quad3d_qgaus`. In the second, the basic one-dimensional routine is `qromb` of §4.3 and the three-dimensional routine is `quad3d_qromb`. The Gaussian quadrature is simpler but its accuracy is not controllable. The Romberg integration lets you specify an accuracy, but is apt to be very slow if you try for too much accuracy. The only difference between the stand-alone version of `trapzd` and the version included here is that we have to add the keyword `RECURSIVE`. The only changes from the stand-alone version of `qromb` are: We have to add `RECURSIVE`; we remove `trapzd` from the list of routines in `USE nr`; we increase `EPS` to 3×10^{-6} . Even this value could be too ambitious for difficult functions. You may want to set `JMAX` to a smaller value than 20 to avoid burning up a lot of computer time. Some people advocate using a smaller `EPS` on the inner quadrature (over z in our routine) than on the outer quadratures (over x or y). That strategy would require separate copies of `qromb`.

```
MODULE quad3d_qgaus_mod

END MODULE quad3d_qgaus_mod

```

f90 **PRIVATE...PUBLIC quad3d_qgaus** By default, all module entities are accessible by a routine that uses the module (unless we restrict the `USE` statement with `ONLY`). In this module, the user needs access only to the routine `quad3d_qgaus`; the variables `xsav`, `ysav` and the procedures `f`, `g`, `h`, and `qgaus` are purely internal. It is good programming practice to prevent duplicate name conflicts or data overwriting by limiting access to only the desired entities. Here the `PRIVATE` statement with no variable names resets the default from `PUBLIC`. Then we include in the `PUBLIC` statement only the function name we want to be accessible.

REAL(SP) :: xsav,ysav In Fortran 90, we generally avoid declaring global variables in `COMMON` blocks. Instead, we give them complete specifications in a module. A deficiency of Fortran 90 is that it does not allow pointers to functions. So here we have to use the fixed-name function `func` for the function to be integrated over. If we could have a pointer to a function as a global variable, then we would just set the pointer to point to the user function (of any name) in the calling program. Similarly the functions `y1`, `y2`, `z1`, and `z2` could also have any name.

CONTAINS Here follow the internal subprograms `f`, `g`, `h`, `qgaus`, and `quad3d_qgaus`. Note that such internal subprograms are all “visible” to each other, i.e., their interfaces are mutually explicit, and do not require `INTERFACE` statements.

RECURSIVE SUBROUTINE qgaus(func,a,b,ss) The `RECURSIVE` keyword is required for the compiler to process correctly any procedure that is invoked again in its body before the return from the first call has been completed. While some compilers may let you get away without explicitly informing them that a routine is recursive, don’t count on it!

    end if
end if
END SUBROUTINE eulsum

```

F₉₀ This routine uses the function `reallocate` in `nrutil` to define a temporary workspace and then, if necessary, enlarge the workspace without destroying the earlier contents. The pointer `wksp` is declared with the `SAVE` attribute. Since Fortran 90 pointers are born “in limbo,” we cannot immediately test whether they are associated or not. Hence the code `if (init)...nullify(wksp)`. Then the line `wksp=>reallocate(wksp,100)` allocates an array of length 100 and points `wksp` to it. On subsequent calls to `eulsum`, if `nterm` ever gets bigger than the size of `wksp`, the call to `reallocate` doubles the size of `wksp` and copies the old contents into the new storage.

You could achieve the same effect as the code `if (init)...nullify(wksp)...wksp=>reallocate(wksp,100)` with a simple `allocate(wksp,100)`. You would then use

reallocate only for increasing the storage if necessary. Don't! The advantage of the above scheme becomes clear if you consider what happens if `eulsum` is invoked *twice* by the calling program to evaluate two different sums. On the second invocation, when `jterm = 1` again, you would be allocating an already allocated pointer. This does not generate an error — it simply leaves the original target inaccessible. Using `reallocate` instead not only allocates a new array of length 100, but also detects that `wksp` had already been associated. It dutifully (and wastefully) copies the first 100 elements of the old `wksp` into the new storage, and, more importantly, deallocates the old `wksp`, reclaiming its storage. While only two invocations of `eulsum` without intervening deallocation of memory would not cause a problem, many such invocations might well. We believe that, as a general rule, the potential for catastrophe from reckless use of `allocate` is great enough that you should *always* deallocate whenever storage is no longer required.

The unnecessary copying of 100 elements when `eulsum` is invoked a second time could be avoided by making `init` an argument. It hardly seems worth it to us.

For Fortran 90 neophytes, note that unlike in C you have to do nothing special to get the contents of the storage a pointer is addressing. The compiler figures out from the context whether you mean the contents, such as `wksp(1:nterm)`, or the address, such as both occurrences of `wksp` in `wksp=>reallocate(wksp,100)`.

`wksp(1:nterm+1)=poly_term(wksp(1:nterm+1),0.5_sp)` The `poly_term` function in `nrutil` tabulates the partial sums of a polynomial, or, equivalently, performs the synthetic division of a polynomial by a monomial.

Small-scale parallelism in `eulsum` is achieved straightforwardly by the use of vector constructions and `poly_term` (which parallelizes recursively).

The routine is not written to take advantage of data parallelism in the (infrequent) case of wanting to sum many different series simultaneously; nor, since `wksp` is a `SAVED` variable, can it be used in many simultaneous instances on a MIMD machine. (You can easily recode these generalizations if you need them.)

END SUBROUTINE ddpoly

```

After the first derivative, factorial constants come in.

f90 `ddpoly(nc:1:-1)=poly_term(c(nc:1:-1),x)` The `poly_term` function in `nrutil` tabulates the partial sums of a polynomial, or, equivalently, performs synthetic division. See §22.3 for a discussion of why `ddpoly` is coded this way.

`fac=cumprod(arth(1.0_sp,1.0_sp,nd))` Here the function `arth` from `nrutil` generates the sequence 1, 2, 3, ... The function `cumprod` then tabulates the cumulative products, thus making a table of factorials.

Notice that `ddpoly` doesn't need an argument to pass N_d , the number of output terms desired by the user: It gets that information from the length of the array `pd` that the user provides for it to fill. It is a minor curiosity that `pd`, declared as `INTENT(OUT)`, can thus be used, on the sly, to pass some `INTENT(IN)` information. (A Fortran 90 brain teaser could be: A subroutine with only `INTENT(OUT)` arguments can be called to print any specified integer. How is this done?)

```
SUBROUTINE poldiv(u,v,q,r)
USE nrtype; USE nrutil, ONLY : assert_eq
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: u,v
REAL(SP), DIMENSION(:), INTENT(OUT) :: q,r
    Given the  $N$  coefficients of a polynomial in  $u$ , and the  $N_v$  coefficients of another polynomial
    in  $v$ , divide the polynomial  $u$  by the polynomial  $v$  (" $u/v$ ") giving a quotient polynomial
    whose coefficients are returned in  $q$ , and a remainder polynomial whose coefficients are
    returned in  $r$ . The arrays  $q$  and  $r$  are of length  $N$ , but only the first  $N - N_v + 1$  elements
    of  $q$  and the first  $N_v - 1$  elements of  $r$  are used. The remaining elements are returned
    as zero.
INTEGER(I4B) :: i,n,nv
n=assert_eq(size(u),size(q),size(r),'poldiv')
nv=size(v)
r(:)=u(:)
q(:)=0.0
do i=n-nv,0,-1
    q(i+1)=r(nv+i)/v(nv)
    r(i+1:nv+i-1)=r(i+1:nv+i-1)-q(i+1)*v(1:nv-1)
end do
r(nv:n)=0.0
END SUBROUTINE poldiv
```

INTEGER(I4B), INTENT(IN) :: mm,kk
REAL(DP), DIMENSION(mm+kk+1), INTENT(IN) :: cof
REAL(DP), DIMENSION(size(x)) :: ratval_v
ratval_v=poly(x,cof(1:mm+1))/(1.0_dp+x*poly(x,cof(mm+2:mm+kk+1)))
END FUNCTION ratval_v

```

★ ★ ★

The routines `recur1` and `recur2` are new in this volume, and do not have Fortran 77 counterparts. First- and second-order linear recurrences are implemented as trivial do-loops on strictly serial machines. On parallel machines, however, they pose different, and quite interesting, programming challenges. Since many calculations can be decomposed into recurrences, it is useful to have general, parallelizable routines available. The algorithms behind `recur1` and `recur2` are discussed in §22.2.

```

RECURSIVE FUNCTION recur1(a,b) RESULT(u)
USE nrtype; USE nrutil, ONLY : assert_eq
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: a,b
REAL(SP), DIMENSION(size(a)) :: u
INTEGER(I4B), PARAMETER :: NPAR_RECUR1=8
  Given vectors a of size n and b of size n-1, returns a vector u that satisfies the first
  order linear recurrence  $u_1 = a_1$ ,  $u_j = a_j + b_{j-1}u_{j-1}$ , for  $j = 2, \dots, n$ . Parallelization is
  via a recursive evaluation.
INTEGER(I4B) :: n,j
n=assert_eq(size(a),size(b)+1,'recur1')
u(1)=a(1)
if (n < NPAR_RECUR1) then           Do short vectors as a loop.
  do j=2,n
    u(j)=a(j)+b(j-1)*u(j-1)
  end do
else
  Otherwise, combine coefficients and recurse on the even components, then evaluate all
  the odd components in parallel.
  u(2:n:2)=recur1(a(2:n:2)+a(1:n-1:2)*b(1:n-1:2), &
    b(3:n-1:2)*b(2:n-2:2))
  u(3:n:2)=a(3:n:2)+b(2:n-1:2)*u(2:n-1:2)
end if
END FUNCTION recur1

```

f90

RECURSIVE FUNCTION `recur1(a,b) RESULT(u)` When a recursive function invokes itself only indirectly through a sequence of function calls, then the function name can be used for the result just as in a nonrecursive function. When the function invokes itself directly, however, as in `recur1`, then another name must be used for the result. If you are hazy on the syntax for `RESULT`, see the discussion of recursion in §21.5.

    END FUNCTION func
END INTERFACE
INTEGER(I4B),PARAMETER :: NTAB=10
REAL(SP), PARAMETER :: CON=1.4_sp,CON2=CON*CON,BIG=huge(x),SAFE=2.0
    Returns the derivative of a function func at a point x by Ridders' method of polynomial
    extrapolation. The value h is input as an estimated initial stepsize; it need not be small,
    but rather should be an increment in x over which func changes substantially. An estimate
    of the error in the derivative is returned as err.
    Parameters: Stepsize is decreased by CON at each iteration. Max size of tableau is set by
    NTAB. Return when error is SAFE worse than the best so far.
INTEGER(I4B) :: ierrmin,i,j
REAL(SP) :: hh
REAL(SP), DIMENSION(NTAB-1) :: errt,fac
REAL(SP), DIMENSION(NTAB,NTAB) :: a
call assert(h /= 0.0, 'dfdrdr arg')
hh=h
a(1,1)=(func(x+hh)-func(x-hh))/(2.0_sp*hh)
err=BIG
fac(1:NTAB-1)=geop(CON2,CON2,NTAB-1)
do i=2,NTAB
    Successive columns in the Neville tableau will go to smaller
    hh=hh/CON
    stepsizes and higher orders of extrapolation.
    a(1,i)=(func(x+hh)-func(x-hh))/(2.0_sp*hh)
    Try new, smaller stepsize.
    do j=2,i
        Compute extrapolations of various orders, requiring no new function evaluations.
        a(j,i)=(a(j-1,i)*fac(j-1)-a(j-1,i-1))/(fac(j-1)-1.0_sp)
    end do
    errt(1:i-1)=max(abs(a(2:i,i)-a(1:i-1,i)),abs(a(2:i,i)-a(1:i-1,i-1)))
    The error strategy is to compare each new extrapolation to one order lower, both at the
    present stepsize and the previous one.
    ierrmin=iminloc(errt(1:i-1))
    if (errt(ierrmin) <= err) then
        If error is decreased, save the improved an-
        err=errt(ierrmin)
        swer.
        dfdrdr=a(1+ierrmin,i)
    end if
    if (abs(a(i,i)-a(i-1,i-1)) >= SAFE*err) RETURN
    If higher order is worse by a significant factor SAFE, then quit early.
end do
END FUNCTION dfdrdr

```

`ierrmin=iminloc(errt(1:i-1))` The function `iminloc` in `nrutil` is useful when you need to know the index of the smallest element in an array.

chebft(:)=matmul(cos(outerprod(arth(0.0_dp,1.0_dp,n),theta)), &
  func(real(cos(theta)*bma+bpa,sp)))*2.0_dp/n
  We evaluate the function at the  $n$  points required by (5.8.7). We accumulate the sum in double precision for safety.
END FUNCTION chebft

```

`chebft(:)=matmul(...)` Here again Fortran 90 produces a very concise parallelizable formulation that requires some effort to decode. Equation (5.8.7) is a product of the matrix of cosines, where the rows are indexed by j and the columns by k , with the vector of function values indexed by k . We use the `outerprod` function in `nrutil` to form the matrix of arguments for the cosine, and rely on the element-by-element application of `cos` to produce the matrix of cosines. `matmul` then takes care of the matrix product. A subtlety is that, while the calculation is being done in double precision to minimize roundoff, the function is assumed to be supplied in single precision. Thus `real(...,sp)` is used to convert the double precision argument to single precision.

```

FUNCTION chebev_s(a,b,c,x)
USE nrtype; USE nrutil, ONLY : nrerror
IMPLICIT NONE
REAL(SP), INTENT(IN) :: a,b,x
REAL(SP), DIMENSION(:), INTENT(IN) :: c
REAL(SP) :: chebev_s

```

Chebyshev evaluation: All arguments are input. c is an array of length M of Chebyshev coefficients, the first M elements of c output from `chebft` (which must have been called

with the same a and b). The Chebyshev polynomial $\sum_{k=1}^M c_k T_{k-1}(y) - c_1/2$ is evaluated at a point $y = [x - (b + a)/2]/[(b - a)/2]$, and the result is returned as the function value.

```

INTEGER(I4B) :: j,m
REAL(SP) :: d,dd,sv,y,y2
if ((x-a)*(x-b) > 0.0) call nrerror('x not in range in chebev_s')
m=size(c)
d=0.0
dd=0.0
y=(2.0_sp*x-a-b)/(b-a)
y2=2.0_sp*y
do j=m,2,-1
    sv=d
    d=y2*d-dd+c(j)
    dd=sv
end do
chebev_s=y*d-dd+0.5_sp*c(1)
END FUNCTION chebev_s

```

Change of variable.

Clenshaw's recurrence.

Last step is different.

```

FUNCTION chebev_v(a,b,c,x)
USE nrtype; USE nrutil, ONLY : nrerror
IMPLICIT NONE
REAL(SP), INTENT(IN) :: a,b
REAL(SP), DIMENSION(:), INTENT(IN) :: c,x
REAL(SP), DIMENSION(size(x)) :: chebev_v
INTEGER(I4B) :: j,m
REAL(SP), DIMENSION(size(x)) :: d,dd,sv,y,y2
if (any((x-a)*(x-b) > 0.0)) call nrerror('x not in range in chebev_v')
m=size(c)
d=0.0
dd=0.0
y=(2.0_sp*x-a-b)/(b-a)
y2=2.0_sp*y

SUBROUTINE pcshft(a,b,d)
USE nrtype; USE nrutil, ONLY : geop
IMPLICIT NONE
REAL(SP), INTENT(IN) :: a,b
REAL(SP), DIMENSION(:), INTENT(INOUT) :: d

```

Polynomial coefficient shift. Given a coefficient array d of length N , this routine generates a coefficient array g of the same length such that $\sum_{k=1}^N d_k y^{k-1} = \sum_{k=1}^N g_k x^{k-1}$, where x and y are related by (5.8.10), i.e., the interval $-1 < y < 1$ is mapped to the interval $a < x < b$. The array g is returned in d .

```

INTEGER(I4B) :: j,n
REAL(SP), DIMENSION(size(d)) :: dd
REAL(SP) :: x
n=size(d)
dd=d*geop(1.0_sp,2.0_sp/(b-a),n)
x=-0.5_sp*(a+b)
d(1)=dd(n)
d(2:n)=0.0
do j=n-1,1,-1
  d(2:n+1-j)=d(2:n+1-j)*x+d(1:n-j)
  d(1)=d(1)*x+dd(j)
end do
END SUBROUTINE pcshft

```

We accomplish the shift by synthetic division, that miracle of high-school algebra.

There is a subtle, but major, distinction between the synthetic division algorithm used in the Fortran 77 version of `pcshft` and that used above. In the Fortran 77 version, the synthetic division (translated to Fortran 90 notation) is

```

      d(1:n)=dd(1:n)
      do j=1,n-1
        do k=n-1,j,-1
          d(k)=x*d(k+1)+d(k)
        end do
      end do

```

while, in Fortran 90, it is

```

      d(1)=dd(n)
      d(2:n)=0.0
      do j=n-1,1,-1
        d(2:n+1-j)=d(2:n+1-j)*x+d(1:n-j)
        d(1)=d(1)*x+dd(j)
      end do

```

As explained in §22.3, these are algebraically — but not algorithmically — equivalent. The inner loop in the Fortran 77 version does not parallelize, because each k value uses the result of the previous one. In fact, the k loop is a synthetic division, which can be parallelized *recursively* (as in the `nrutil` routine `poly_term`), but not simply

vectorized. In the Fortran 90 version, since not one but $n-1$ successive synthetic divisions are to be performed (by the outer loop), it is possible to reorganize the calculation to allow vectorization.

```

f90

temp=geop(spread(1.0_dp,1,npt),xs,ncof) The design matrix u_{ij} is defined for $i = 1, \dots, \text{npts}$ by

$$u_{ij} = \begin{cases} w_i x_i^{j-1}, & j = 1, \dots, m+1 \\ -b_i x_i^{j-m-2}, & j = m+2, \dots, n \end{cases} \quad (\text{B5.12})$$

The first case in equation (B5.12) is computed in parallel by constructing the matrix temp equal to

$$\begin{bmatrix} 1 & x_1 & x_1^2 & \cdots \\ 1 & x_2 & x_2^2 & \cdots \\ 1 & x_3 & x_3^2 & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix}$$

and then multiplying by the matrix spread(wt,2,mm+1), which is just

$$\begin{bmatrix} w_1 & w_1 & w_1 & \cdots \\ w_2 & w_2 & w_2 & \cdots \\ w_3 & w_3 & w_3 & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix}$$

(Remember that multiplication using * means element-by-element multiplication, not matrix multiplication.) A similar construction is used for the second part of the design matrix.

Chapter B6. Special Functions

f90 A Fortran 90 intrinsic function such as `sin(x)` is both *generic* and *elemental*. Generic means that the argument `x` can be any of multiple intrinsic data types and kind values (in the case of `sin`, any real or complex kind). Elemental means that `x` need not be a scalar, but can be an array of any rank and shape, in which case the calculation of `sin` is performed independently for each element.

Ideally, when we implement more complicated special functions in Fortran 90, as we do in this chapter, we would make them, too, both generic and elemental. Unfortunately, the language standard does not completely allow this. User-defined elemental functions are prohibited in Fortran 90, though they will be allowed in Fortran 95. And, there is no fully automatic way of providing for a single routine to allow arguments of multiple data types or kinds — nothing like C++’s “class templates,” for example.

However, don’t give up hope! Fortran 90 does provide a powerful mechanism for overloading, which can be used (perhaps not always with a maximum of convenience) to *simulate* both generic and elemental function features. In most cases, when we implement a special function with a scalar argument, `gammln(x)` say, we will also implement a corresponding vector-valued function of vector argument that evaluates the special function for each component of the vector argument. We will then overload the scalar and vector version of the function onto the same function name. For example, within the `nr` module are the lines

```
INTERFACE gammln
  FUNCTION gammln_s(xx)
    USE nrtype
    REAL(SP), INTENT(IN) :: xx
    REAL(SP) :: gammln_s
  END FUNCTION gammln_s

  FUNCTION gammln_v(xx)
    USE nrtype
    REAL(SP), DIMENSION(:), INTENT(IN) :: xx
    REAL(SP), DIMENSION(size(xx)) :: gammln_v
  END FUNCTION gammln_v
END INTERFACE
```

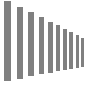

which can be included by a statement like “`USE nr, ONLY: gammln,`” and then allow you to write `gammln(x)` without caring (or even thinking about) whether `x` is a scalar or a vector. If you want arguments of even higher rank (matrices, and so forth), you can provide these yourself, based on our models, and overload them, too.

That takes care of “elemental”; what about “generic”? Here, too, overloading provides an acceptable, if not perfect, solution. Where double-precision versions of special functions are needed, you can in many cases easily construct them from our provided routines by changing the variable kinds (and any necessary convergence

parameters), and then additionally overload them onto the same generic function names. (In general, in the interest of brevity, we will not ourselves do this for the functions in this chapter.)

At first meeting, Fortran 90's overloading capability may seem trivial, or merely cosmetic, to the Fortran 77 programmer; but one soon comes to rely on it as an important conceptual simplification. Programming at a "higher level of abstraction" is usually more productive than spending time "bogged down in the mud." Furthermore, the use of overloading is generally fail-safe: If you invoke a generic name with arguments of shapes or types for which a specific routine has not been defined, the compiler tells you about it.

We won't reprint the module `nr`'s interface blocks for all the routines in this chapter. When you see routines named `something_s` and `something_v`, below, you can safely assume that the generic name `something` is defined in the module `nr` and overloaded with the two specific routine names. A full alphabetical listing of all the interface blocks in `nr` is given in Appendix C2.

 Given our heavy investment, in this chapter, in overloadable vector-valued special function routines, it is worth discussing whether this effort is simply a stopgap measure for Fortran 90, soon to be made obsolete by Fortran 95's provision of user-definable `ELEMENTAL` procedures. The answer is "not necessarily," and takes us into some speculation about the future of SIMD, versus MIMD, computing.

Elemental procedures, while applying the same executable code to each element, do not insist that it be feasible to perform all the parallel calculations in lockstep. That is, elemental procedures can have tests and branches (`if-then-else` constructions) that result in different elements being calculated by totally different pieces of code, in a fashion that can only be determined at run time. For true 100% MIMD (multiple instruction, multiple data) machines, this is not a problem: individual processors do the individual element calculations asynchronously.

However, virtually none of today's (and likely tomorrow's) largest-scale parallel supercomputers are 100% MIMD in this way. While modern parallel supercomputers increasingly have MIMD features, they continue to reward the use of SIMD (single instruction, multiple data) code with greater computational speed, often because of hardware pipelining or vector processing features within the individual processors. The use of Fortran 90 (or, for that matter Fortran 95) in a data-parallel or SIMD mode is thus by no means superfluous, or obviated by Fortran 95's `ELEMENTAL` construction.

The problem we face is that parallel calculation of special function values often doesn't fit well into the SIMD mold: Since the calculation of the value of a special function typically requires the convergence of an iterative process, as well as possible branches for different values of arguments, it cannot *in general* be done efficiently with "lockstep" SIMD programming.

Luckily, in particular cases, including most (but not all) of the functions in this chapter, one can in fact make reasonably good parallel implementations with the SIMD tools provided by the language. We will in fact see a number of different tricks for accomplishing this in the code that follows.

We are interested in demonstrating SIMD techniques, but we are not completely impractical. None of the data-parallel implementations given below are too inefficient on a scalar machine, and some may in fact be faster than Fortran 95's `ELEMENTAL`

alternative, or than do-loops over calls to the scalar version of the function. On a scalar machine, how can this be? We have already, above, hinted at the answer: (i) most modern scalar processors can overlap instructions to some degree, and data-parallel coding often provides compilers with the ability to accomplish this more efficiently; and (ii) data-parallel code can sometimes give better cache utilization.

```

call `assert(xx > 0.0, 'gammln_s arg')` We use the `nrutil` routine `assert` for functions that have restrictions on the allowed range of arguments. One could instead have used an `if` statement with a call to `nrerror`; but we think that the uniformity of using `assert`, and the fact that its logical arguments read the “desired” way, not the “erroneous” way, make for a clearer programming style. In the vector version, the `assert` line is: `call assert(all(xx > 0.0), 'gammln_v arg')`

Notice that the scalar and vector versions achieve parallelism in quite different ways, something that we will see many times in this chapter. In the scalar case, parallelism (at least small-scale) is achieved through constructions like

```
sum(coef(:)/arth(x+1.0_dp,1.0_dp,size(coef)))
```

Here vector utilities construct the series $x + 1, x + 2, \dots$ and then sum a series with these terms in the denominators and a vector of coefficients in the numerators. (This code may seem terse to Fortran 90 novices, but once you get used to it, it is quite clear to read.)

In the vector version, by contrast, parallelism is achieved across the components of the vector argument, and the above series is evaluated sequentially as a do-loop. Obviously the assumption is that the length of the vector argument is much longer than the very modest number (here, 6) of terms in the sum.

where (.not. mask) factrl_v=a(n+1)
END FUNCTION factrl_v

```

unpack(exp(gammln(pack(n,mask)+1.0_sp)),mask,0.0_sp) Here we meet the first of several solutions to a common problem: How shall we get answers, from an external vector-valued function, for just a *subset* of vector arguments, those defined by a mask? Here we use what we call the “pack-unpack” solution: Pack up all the arguments using the mask, send them to the function, and unpack the answers that come back. This packing and unpacking is not without cost (highly dependent on machine architecture, to be sure), but we hope to “earn it back” in the parallelism of the external function.

where (.not. mask) factrl_v=a(n+1) In some cases we might take care of the .not. mask case directly within the unpack construction, using its third (“FIELD=”) argument to provide the not-unpacked values. However, there is no guarantee that the compiler won’t evaluate all components of the “FIELD=” array, if it finds it efficient to do so. Here, since the index of a(n+1) would be out of range, we can’t do it this way. Thus the separate where statement.

```

call assert(x >= 0.0, a > 0.0, 'gammq_s args') The generic routine assert in nrutil is overloaded with variants for more than one logical assertion, so you can make more than one assertion about argument ranges.

gammq_v=merge(gser(a,merge(x,0.0_sp,mask)), &
1.0_sp-gcf(a,merge(x,0.0_sp,.not. mask)),mask) Here we meet the *second* solution to the problem of getting masked values from an external vector function. (For the first solution, see note to factrl, above.) We call this one “merge with dummy values”: Inappropriate values of the argument x (as determined by mask) are set to zero before gser, and later gcf, are called, and the supernumerary answers returned are discarded by a final merge. The assumption here is that the dummy value sent to the function (here, zero) is a special value that computes extremely fast, so that the overhead of computing and returning the supernumerary function values is outweighed by the parallelism achieved on the nontrivial components of x. Look at gser_v and gcf_v below to judge whether this assumption is realistic in this case.

f90 REAL(SP), OPTIONAL, INTENT(OUT) :: gln Normally, an OPTIONAL argument will be INTENT(IN) and be used to provide a less-often-used extra input argument to a function. Here, the OPTIONAL argument is INTENT(OUT), used to provide a useful value that is a byproduct of the main calculation.

Also note that although $x \geq 0$ is required, we omit our usual `call assert` check for this, because `gser` is supposed to be called only by `gammq` or `gammq` — and these routines supply the argument checking themselves.

do n=1,ITMAX...end do...if (n > ITMAX)... This is typical code in Fortran 90 for a loop with a maximum number of iterations, relying on Fortran 90's guarantee that the index of the do-loop will be available after normal completion of the loop with a predictable value, greater by one than the upper limit of the loop. If the exit statement within the loop is ever taken, the if statement is guaranteed to fail; if the loop goes all the way through ITMAX cycles, the if statement is guaranteed to succeed.

 zero=(x == 0.0)...where (zero) gser_v=0.0...converged=zero This is the code that provides for very low overhead calculation of zero arguments, as is assumed by the merge-with-dummy-values strategy in `gammq` and `gammq`. Zero arguments are “pre-converged” and are never the holdouts in the convergence test.

```
FUNCTION gcf_s(a,x,gln)

★ ★ ★

```

FUNCTION erf_s(x)
USE nrtype
USE nr, ONLY : gammp
IMPLICIT NONE
REAL(SP), INTENT(IN) :: x
REAL(SP) :: erf_s
  Returns the error function erf(x).
erf_s=gammp(0.5_sp,x**2)
if (x < 0.0) erf_s=-erf_s
END FUNCTION erf_s

```

```

FUNCTION erf_v(x)
USE nrtype
USE nr, ONLY : gammp
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: x
REAL(SP), DIMENSION(size(x)) :: erf_v
erf_v=gammp(spread(0.5_sp,1,size(x)),x**2)
where (x < 0.0) erf_v=-erf_v
END FUNCTION erf_v

```

erf_v=gammp(spread(0.5_sp,1,size(x)),x**2) Yes, we do have an overloaded vector version of gammp, but it is vectorized on *both* its arguments. Thus, in a case where we want to vectorize on only *one* argument, we need a spread construction. In many contexts, Fortran 90 automatically makes scalars conformable with arrays (i.e., it automatically spreads them to the shape of the array); but the language does *not* do so when trying to match a generic function or subroutine call to a specific overloaded name. Perhaps this is wise; it is safer to prevent “accidental” invocations of vector-specific functions. Or, perhaps it is an area where the language could be improved.

```

FUNCTION erfc_s(x)
USE nrtype
USE nr, ONLY : gammp,gammq
IMPLICIT NONE
REAL(SP), INTENT(IN) :: x
REAL(SP) :: erfc_s
  Returns the complementary error function erfc(x).
erfc_s=merge(1.0_sp+gammp(0.5_sp,x**2),gammq(0.5_sp,x**2), x < 0.0)
END FUNCTION erfc_s

```

erfc_s=merge(1.0_sp+gammp(0.5_sp,x**2),gammq(0.5_sp,x**2), x < 0.0)
An example of our use of merge as an idiom for a conditional expression. Once you get used to these, you’ll find them just as clear as the multiline if...then...else alternative.

```

FUNCTION erfc_v(x)
USE nrtype
USE nr, ONLY : gammq,gammq
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: x
REAL(SP), DIMENSION(size(x)) :: erfc_v
LOGICAL(LGT), DIMENSION(size(x)) :: mask
mask = (x < 0.0)
erfc_v=merge(1.0_sp+gammq(spread(0.5_sp,1,size(x)), &
    merge(x,0.0_sp,mask)**2),gammq(spread(0.5_sp,1,size(x)), &
    merge(x,0.0_sp,.not. mask)**2),mask)
END FUNCTION erfc_v

```

f90 `erfc_v=merge(1.0_sp+...)` Another example of the “merge with dummy values” idiom described on p. 1090. Here positive values of x in the call to `gammq`, and negative values in the call to `gammq`, are first set to the dummy value zero. The value zero is a special argument that computes very fast. The unwanted dummy function values are then discarded by the final outer merge.

★ ★ ★

```

FUNCTION erfcc_s(x)

REAL(SP), DIMENSION(10) :: coef = (/ -1.26551223_sp, 1.00002368_sp, &
    0.37409196_sp, 0.09678418_sp, -0.18628806_sp, 0.27886807_sp, &
    -1.13520398_sp, 1.48851587_sp, -0.82215223_sp, 0.17087277_sp /)
z=abs(x)
t=1.0_sp/(1.0_sp+0.5_sp*z)
erfcc_v=t*exp(-z*z+poly(t,coef))
where (x < 0.0) erfcc_v=2.0_sp-erfcc_v
END FUNCTION erfcc_v

```

f90 `erfcc_v=t*exp(-z*z+poly(t,coef))` The vector code is identical to the scalar, because the `nrutil` routine `poly` has overloaded cases for the evaluation of a polynomial at a single value of the independent variable, and at multiple values. One *could* also overload a version with a matrix of coefficients whose columns could be used for the simultaneous evaluation of different polynomials at different values of independent variable. The point is that as long as there are differences in the shapes of at least one argument, the intended version of `poly` can be discerned by the compiler.

```

expint does not readily parallelize, and we thus don't provide a vector version. For syntactic convenience you could make a vector version with a do-loop over calls to this scalar version; or, in Fortran 95, you can of course make the function ELEMENTAL.

* * *

```

FUNCTION ei(x)
USE nrtype; USE nrutil, ONLY : assert,nrerror
IMPLICIT NONE
REAL(SP), INTENT(IN) :: x
REAL(SP) :: ei
INTEGER(I4B), PARAMETER :: MAXIT=100
REAL(SP), PARAMETER :: EPS=epsilon(x),FPMIN=tiny(x)/EPS

```

Computes the exponential integral $Ei(x)$ for $x > 0$.

Parameters: MAXIT is the maximum number of iterations allowed; EPS is the relative error, or absolute error near the zero of Ei at $x = 0.3725$; FPMIN is a number near the smallest representable floating-point number; EULER (in nrtype) is Euler's constant γ .

```

INTEGER(I4B) :: k
REAL(SP) :: fact,prev,sm,term
call assert(x > 0.0, 'ei arg')
if (x < FPMIN) then
    ei=log(x)+EULER
else if (x <= -log(EPS)) then
    sm=0.0
    fact=1.0
    do k=1,MAXIT
        fact=fact*x/k
        term=fact/k
        sm=sm+term
        if (term < EPS*sm) exit
    end do
    if (k > MAXIT) call nrerror('series failed in ei')
    ei=sm+log(x)+EULER
else
    sm=0.0
    term=1.0
    do k=1,MAXIT
        prev=term
        term=term*k/x
        if (term < EPS) exit
        if (term < prev) then
            sm=sm+term
        else
            sm=sm-prev
            exit
        end if
    end do
    if (k > MAXIT) call nrerror('asymptotic failed in ei')
    ei=exp(x)*(1.0_sp+sm)/x
end if
END FUNCTION ei

```

Special case: avoid failure of convergence test because of underflow.

Use power series.

Use asymptotic series.

Start with second term.

Since final sum is greater than one, term itself approximates the relative error.

Still converging: add new term.

Diverging: subtract previous term and exit.

ei does not readily parallelize, and we thus don't provide a vector version. For syntactic convenience you could make a vector version with a do-loop over calls to this scalar version; or, in Fortran 95, you can of course make the function `ELEMENTAL`.

f90

`d=merge(FPMIN,d, abs(d)<FPMIN)` The scalar version does this with an `if`. Why does it become a `merge` here in the vector version, rather than a `where`? Because we are already inside a “`where (.not.converged)`” block, and Fortran 90 doesn’t allow nested `where`’s! (Fortran 95 *will* allow nested `where`’s.)

```

where $(\text{mask}) \dots \text{bessj0_v} = \text{poly}(y, r, \text{mask}) / \text{poly}(y, s, \text{mask})$ Here we meet the *third* solution to the problem of getting masked values from an external vector function. (For the other two solutions, see notes to `factrl`, p. 1087, and `gamm`, p. 1090.) Here we simply evade all responsibility and pass the mask into every routine that is supposed to be masked. Let it be somebody else's problem! That works here because your hardworking authors have overloaded the `nrutil` routine `poly` with a masked vector version. More typically, of course, it becomes *your* problem, and you have to remember to write masked versions of all the vector routines that you call in this way. (We'll meet examples of this later.)

f90 Notice that the vector routine is *exactly* the same as the scalar routine, but operates only on vectors, and that nothing in the routine is specific to any level of precision or kind type of real variable. Cases like this make us wish that Fortran 90 provided for “template” types that could automatically take the type and shape of the actual arguments. (Such facilities are available in other, more object-oriented languages such as C++.)

```

Downwards recurrence from an even m here computed.

j sum will alternate between 0 and 1; when it is 1, we accumulate in sum the even terms in (5.5.16).

The downward recurrence.

Renormalize to prevent overflows.

Accumulate the sum.
Change 0 to 1 or vice versa.
Save the unnormalized answer.

Compute (5.5.16) and use it to normalize the answer.

The `bessj` routine does not conveniently parallelize with Fortran 90's language constructions, but Bessel functions are of sufficient importance that we feel the need for a parallel version nevertheless. The basic method adopted below is to encapsulate as contained vector functions two separate algorithms, one for the case $x \leq n$, the other for $x > n$. Both of these have masks as input arguments; within each routine, however, they immediately revert to the pack-unpack method. The choice to pack in the subsidiary routines, rather than in the main routine, is arbitrary; the main routine is supposed to be a little clearer this way.

if (exponent(bj) > IEXP) then... In the Fortran 77 version of this routine, we scaled the variables by 10^{-10} whenever bj was bigger than 10^{10} . On a machine with a large exponent range, we could improve efficiency by scaling less often. In order to remain portable, however, we used the conservative value of 10^{10} . An elegant way of handling renormalization is provided by the Fortran 90 intrinsic functions that manipulate real numbers. We test with `if (exponent(bj) > IEXP)` and then if necessary renormalize with `bj=scale(bj,-IEXP)` and similarly for the other variables. Our conservative choice is to set `IEXP=maxexponent(x)/2`. Note that an added benefit of scaling this way is that only the exponent of each variable is modified; no roundoff error is introduced as it can be if we do a floating-point division instead.

f90

`bessj_v=... bessj_v=merge(bessjgt_v(...),bessj_v,...)` The vector `bessj_v` is set once (with a mask) and then merged with *itself*, along with the vector result of the `bessjgt_v` call. Thus are the two evaluation methods combined. (A third case, where an argument is zero, is then handled by an immediately following `where`.)

Equation (6.7.13).
Evaluate CF2 by modified Lentz's method (§5.2).

Equations (6.7.6) – (6.7.10).

Scale original J_ν and J'_ν .

Upward recurrence of Y_ν .

Yes there is a vector version `bessjy_v`. Its general scheme is to have a bunch of contained functions for various cases, and then combine their outputs (somewhat like `bessj_v`, above, but much more complicated). A listing runs to about four printed pages, and we judge it to be of not much interest, so we will not include it here. (It is included on the machine-readable media.)

```

Evaluate CF2 by Steed's algorithm (§5.2), which is OK because there can be no zero denominators.

Initializations for recurrence (6.7.35).

First term in equation (6.7.34).

Need only test convergence of sum, since CF2 itself converges more quickly.

Omit the factor $\exp(-x)$ to scale all the returned functions by $\exp(x)$ for $x \geq \text{XMIN}$.

Get I_μ from Wronskian. Scale original I_ν and I'_ν .

Upward recurrence of K_ν .

bessik does not readily parallelize, and we thus don't provide a vector version. Since airy, immediately following, requires bessik, we don't have a vector version of it, either.

All those if's (not where's) may strike you as odd in a vector routine, but it is vectorized only on x , the dependent variable, not on the scalar indices l and m . Much harder to write a routine that is parallel for a vector of arbitrary triplets (l, m, x) . Try it!

f90 `b=cmplx(1.0_sp,-pix2,kind=spc)` It's a good idea *always* to include the `kind=` parameter when you use the `cmplx` intrinsic. The reason is that, perhaps counterintuitively, the result of `cmplx` is not determined by the kind of its arguments, but is rather the “default complex kind.” Since that default may not be what you think it is (or what `spc` is defined to be), the desired kind should be specified explicitly.

`c=real(cs)` And why not specify a `kind=` parameter here, where it is also optionally allowed? Our answer is that the `real` intrinsic actually merges two different usages. When its argument is complex, it is the counterpart of `aimag` and returns a value whose kind is determined by the kind of its argument. In fact `aimag` doesn't even allow an optional `kind` parameter, so we never put one in the corresponding use of `real`. The other usage of `real` is for “casting,” that is, converting one real type to another (e.g., double precision to single precision, or vice versa). Here we *always* include a `kind` parameter, since otherwise the result is the default real kind, with the same dangers mentioned in the previous paragraph.

f90 REAL(SP), DIMENSION(NMAX), SAVE :: c=(/ (0.0_sp,i=1,NMAX) /) This is one way to give initial values to an array. Actually, we're somewhat nervous about using the "implied do-loop" form of the array constructor, as above, because our parallel compilers might not always be smart enough to execute the constructor in parallel. In this case, with NMAX=6, the damage potential is quite minimal. An alternative way to initialize the array would be with a data statement, "DATA c /NMAX*0.0_sp/"; however, this is not considered good Fortran 90 style, and there is no reason to think that it would be faster.

c(1:NMAX)=exp(-(arth(1,2,NMAX)*H)**2) Another example where the arth function of nrutil comes in handy. Otherwise, this would be

```

do i=1,NMAX
  c(i)=exp(-((2.0_sp*i-1.0_sp)*H)**2)
end do

```

arth(n0+1,2,NMAX)...arth(n0-1,-2,NMAX)...geop(ec,ec**2,NMAX) These are not just notationally convenient for generating the sequences $(n_0+1, n_0+3, n_0+5, \dots)$, $(n_0-1, n_0-3, n_0-5, \dots)$, and (ec, ec^3, ec^5, \dots) . They also may allow parallelization with parallel versions of arth and geop, such as those in nrutil.

END FUNCTION rj_v

```

`unpack(3.0_sp*(rc(pack(rho,mask),pack(tau,mask))...),mask,0.0_sp)`

If you're willing to put up with fairly unreadable code, you can use the pack-unpack trick (for getting a masked subset of components out of a vector function) right in-line, as here. Of course the "outer level" that is seen by the enclosing where construction has to contain only objects that have the same shape as the mask that goes with the where. Because it is so hard to read, we don't like to do this very often. An alternative would be to use CONTAINS to incorporate short, masked "wrapper functions" for the functions used in this way.

```

f90 Notice that the real array (of length 4) `ry` is immediately mapped into a complex array of length 2, and that the process is reversed at the end of the routine with `rdyds`. In Fortran 77 no such mapping is necessary: the calling program sends real arguments, and the Fortran 77 `hypdrv` simply interprets what is sent as complex. Fortran 90's stronger typing does not encourage (and, practically, does not allow) this convenience; but it is a small price to pay for the vastly increased error-checking capabilities of a strongly typed language.

Chapter B7. Random Numbers

One might think that good random number generators, including those in Volume 1, should last forever. The world of computing changes very rapidly, however:

- When Volume 1 was published, it was unusual, except on the fastest supercomputers, to “exhaust” a 32-bit random number generator, that is, to call for all 2^{32} sequential random values in its periodic sequence. Now, this is feasible, and not uncommon, on fast desktop workstations. A useful generator today must have a minimum of 64 bits of state space, and generally somewhat more.
- Before Fortran 90, the Fortran language had no standardized calling sequence for random numbers. Now, although there is still no standard *algorithm* defined by the language (rightly, we think), there is at least a standard calling sequence, exemplified in the intrinsics `random_number` and `random_seed`.
- The rise of parallel computing places new algorithmic demands on random generators. The classic algorithms, which compute each random value from the previous one, evidently need generalization to a parallel environment.
- New algorithms and techniques have been discovered, in some cases significantly faster than their predecessors.

These are the reasons that we have decided to implement, in Fortran 90, different uniform random number generators from those in Volume 1’s Fortran 77 implementations. We hasten to add that there is nothing wrong with any of the generators in Volume 1. That volume’s `ran0` and `ran1` routines are, to our knowledge, completely adequate as 32-bit generators; `ran2` has a 64-bit state space, and our previous offer of \$1000 for *any* demonstrated failure in the algorithm has never yet been claimed (see [1]).

Before we launch into the discussion of parallelizable generators with Fortran 90 calling conventions, we want to attend to the continuing needs of longtime “`x=ran(idum)`” users with purely serial machines. If you are a satisfied user of Volume 1’s `ran0`, `ran1`, or `ran2` Fortran 77 versions, you are in this group. The following routine, `ran`, preserves those routines’ calling conventions, is considerably faster than `ran2`, and does not suffer from the old `ran0` or `ran1`’s 32-bit period exhaustion limitation. It is completely portable to all Fortran 90 environments. We recommend `ran` as the plug-compatible replacement for the old `ran0`, `ran1`, and `ran2`, and we happily offer exactly the same \$1000 reward terms as were (and are still) offered on the old `ran2`.

```

FUNCTION ran(idum)
IMPLICIT NONE
INTEGER, PARAMETER :: K4B=selected_int_kind(9)
INTEGER(K4B), INTENT(INOUT) :: idum
REAL :: ran
    "Minimal" random number generator of Park and Miller combined with a Marsaglia shift
    sequence. Returns a uniform random deviate between 0.0 and 1.0 (exclusive of the endpoint
    values). This fully portable, scalar generator has the "traditional" (not Fortran 90) calling
    sequence with a random deviate as the returned function value: call with idum a negative
    integer to initialize; thereafter, do not alter idum except to reinitialize. The period of this
    generator is about  $3.1 \times 10^{18}$ .
INTEGER(K4B), PARAMETER :: IA=16807, IM=2147483647, IQ=127773, IR=2836
REAL, SAVE :: am
INTEGER(K4B), SAVE :: ix=-1, iy=-1, k

    ix=ieor(777755555,abs(idum))
    idum=abs(idum)+1                       Set idum positive.
end if
ix=ieor(ix,ishft(ix,13))                  Marsaglia shift sequence with period  $2^{32} - 1$ .
ix=ieor(ix,ishft(ix,-17))
ix=ieor(ix,ishft(ix,5))
k=iy/IQ                                    Park-Miller sequence by Schrage's method,
iy=IA*(iy-k*IQ)-IR*k                       period  $2^{31} - 2$ .
if (iy < 0) iy=iy+IM
ran=am*ior(iand(IM,ieor(ix,iy)),1)         Combine the two generators with masking to
END FUNCTION ran                          ensure nonzero value.

```

This is a good place to discuss a new bit of algorithmics that has crept into `ran`, above, and even more strongly affects all of our new random number generators, below. Consider:

```

ix=ieor(ix,ishft(ix,13))
ix=ieor(ix,ishft(ix,-17))
ix=ieor(ix,ishft(ix,5))

```

These lines update a 32-bit integer `ix`, which cycles pseudo-randomly through a full period of $2^{32} - 1$ values (excluding zero) before repeating. Generators of this type have been extensively explored by Marsaglia (see [2]), who has kindly communicated some additional results to us in advance of publication. For convenience, we will refer to generators of this sort as "Marsaglia shift registers."

Useful properties of Marsaglia shift registers are (i) they are very fast on most machines, since they use only fast logical operations, and (ii) the bit-mixing that they induce is quite different in character from that induced by arithmetic operations such as are used in linear congruential generators (see Volume 1) or lagged Fibonacci generators (see below). Thus, the combination of a Marsaglia shift register with another, algorithmically quite different generator is a powerful way to suppress any residual correlations or other weaknesses in the other generator. Indeed, Marsaglia finds (and we concur) that the above generator (with constants 13, -17, 5, as shown) is *by itself* about as good as any 32-bit random generator.

Here is a very brief outline of the theory behind these generators: Consider the 32 bits of the integer as components in a vector of length 32, in a linear space where addition and multiplication are done modulo 2. Noting that exclusive-or (`ieor`) is the same as addition, each of the three lines in the updating can be written as the action of a 32×32 matrix on a vector, where the matrix is all zeros except for ones on

the diagonal, and on exactly one super- or subdiagonal (corresponding to positive or negative second arguments in `ishft`). Denote this matrix as \mathbf{S}_k , where k is the shift argument. Then, one full step of updating (three lines of code, above) corresponds to multiplication by the matrix $\mathbf{T} \equiv \mathbf{S}_{k_3}\mathbf{S}_{k_2}\mathbf{S}_{k_1}$.

One next needs to find triples of integers (k_1, k_2, k_3) , for example $(13, -17, 5)$, that give the full $M \equiv 2^{32} - 1$ period. Necessary and sufficient conditions are that $\mathbf{T}^M = \mathbf{1}$ (the identity matrix), and that $\mathbf{T}^N \neq \mathbf{1}$ for these five values of N : $N = 3 \times 5 \times 17 \times 257$, $N = 3 \times 5 \times 17 \times 65537$, $N = 3 \times 5 \times 257 \times 65537$, $N = 3 \times 17 \times 257 \times 65537$, $N = 5 \times 17 \times 257 \times 65537$. (Note that each of the five prime factors of M is omitted one at a time to get the five values of N .) The required large powers of \mathbf{T} are readily computed by successive squarings, requiring only on the order of $32^3 \log M$ operations. With this machinery, one can find full-period triples (k_1, k_2, k_3) by exhaustive search, at reasonable cost.

Not all such triples are equally good as generators of random integers, however. Marsaglia subjects candidate values to a battery of tests for randomness, and we have ourselves applied various tests. This stage of winnowing is as much art as science, because all 32-bit generators can be made to exhibit signs of failure due to period exhaustion (if for no other reason). “Good” triples, in order of our preference, are $(13, -17, 5)$, $(5, -13, 6)$, $(5, -9, 7)$, $(13, -17, 15)$, $(16, -7, 11)$. When a full-period triple is good, its reverse is also full-period, and also generally good. A good *quadruple* due to Marsaglia (generalizing the above in the obvious way) is $(-4, 8, -1, 5)$. We would not recommend relying on any single Marsaglia shift generator (nor on any other simple generator) *by itself*. Two or more generators, of quite different types, should be combined [1].

★ ★ ★

Let us now discuss explicitly the needs of *parallel* random number generators. The general scheme, from the user’s perspective, is that of Fortran 90’s intrinsic `random_number`: A statement like `call ran1(harvest)` (where `ran1` will be one of our portable replacements for the compiler-dependent `random_number`) should fill the real array `harvest` with pseudo-random real values in the range $(0, 1)$. Of course, we want the underlying machinery to be completely parallel, that is, no do-loops of order $N \equiv \text{size}(\text{harvest})$.

A first design decision is whether to replicate the state-space across the parallel dimension N , i.e., whether to reserve storage for essentially N scalar generators. Although there are various schemes that avoid doing this (e.g., mapping a single, smaller, state space into N different output values on each call), we think that it is a memory cost well worth paying in return for achieving a less exotic (and thus better tested) algorithm. However, this choice dictates that we must keep the state space *per component* quite small. We have settled on five or fewer 32-bit words of state space per component as a reasonable limit. Some otherwise interesting and well tested methods (such as Knuth’s subtractive generator, implemented in Volume 1 as `ran3`) are ruled out by this constraint.

A second design decision is how to initialize the parallel state space, so that different parallel components produce different sequences, and so that there is an acceptable degree of randomness *across* the parallel dimension, as well as *between successive calls* of the generator. Each component starts its life with one and only one unique identifier, its component index n in the range $1 \dots N$. One is

tempted simply to hash the values n into the corresponding components of initial state space. “Random” hashing is a bad idea, however, because different n ’s will produce identical 32-bit hash results by chance when N is no larger than $\sim 2^{16}$. We therefore prefer to use a kind of reversible pseudo-encryption (similar to the routine `psdes` in Volume 1 and below) which guarantees causally that different n ’s produce different state space initializations.

f90 The machinery for allocating, deallocating, and initializing the state space, including provision of a user interface for getting or putting the contents of the state space (as in the intrinsic `random_seed`) is fairly complicated. Rather than duplicate it in each different random generator that we provide, we have consolidated it in a single module, `ran_state`, whose contents we will now discuss. Such a discussion is necessarily technical, if not arcane; on first reading, you may wish to skip ahead to the actual new routines `ran0`, `ran1`, and `ran2`. If you do so, you will need to know only that `ran_state` provides each vector random routine with five 32-bit vectors of state information, denoted `iran`, `jran`, `kran`, `mrans`, `nrans`. (The overloaded scalar generators have five corresponding 32-bit scalars, denoted `iran0`, etc.)

MODULE `ran_state`

This module supports the random number routines `ran0`, `ran1`, `ran2`, and `ran3`. It provides each generator with five integers (for vector versions, five vectors of integers), for use as internal state space. The first three integers (`iran`, `jran`, `kran`) are maintained as nonnegative values, while the last two (`mrans`, `nrans`) have 32-bit nonzero values. Also provided by this module is support for initializing or reinitializing the state space to a desired standard sequence number, hashing the initial values to random values, and allocating and deallocating the internal workspace.

```
USE nrtype
IMPLICIT NONE
INTEGER, PARAMETER :: K4B=selected_int_kind(9)
    Independent of the usual integer kind I4B, we need a kind value for (ideally) 32-bit integers.
INTEGER(K4B), PARAMETER :: hg=huge(1_K4B), hgm=-hg, hgng=hgm-1
INTEGER(K4B), SAVE :: lenran=0, seq=0
INTEGER(K4B), SAVE :: iran0,jran0,kran0,nran0,mrans0,ran5
INTEGER(K4B), DIMENSION(:,:), POINTER, SAVE :: ranseeds
INTEGER(K4B), DIMENSION(:), POINTER, SAVE :: iran,jran,kran, &
    nran,mrans,ranv
REAL(SP), SAVE :: amm
INTERFACE ran_hash
    Scalar and vector versions of the hashing procedure.
    MODULE PROCEDURE ran_hash_s, ran_hash_v
END INTERFACE
CONTAINS
```

(We here intersperse discussion with the listing of the module.) The module defines `K4B` as an integer `KIND` that is intended to be 32 bits. If your machine doesn’t have 32-bit integers (hard to believe!) this will be caught later, and an error message generated. The definition of the parameters `hg`, `hgm`, and `hgng` makes an assumption about 32-bit integers that goes beyond the strict Fortran 90 integer model, that the magnitude of the most negative representable integer is greater by one than that of the most positive representable integer. This is a property of the *two’s complement arithmetic* that is used on virtually all modern machines (see, e.g., [3]).

The global variables `rans` (for scalar) and `ranv` (for vector) are used by all of our routines to store the *integer* value associated with the most recently returned call. You can access these (with a “`USE ran_state`” statement) if you want integer, rather than real, random deviates.

The first routine, `ran_init`, is called by routines later in the chapter to initialize their state space. It is *not* intended to be called from a user's program.

```

SUBROUTINE ran_init(length)
USE nrtype; USE nrutil, ONLY : arth,nrerror,reallocate
IMPLICIT NONE
INTEGER(K4B), INTENT(IN) :: length
    Initialize or reinitialize the random generator state space to vectors of size length. The
    saved variable seq is hashed (via calls to the module routine ran_hash) to create unique
    starting seeds, different for each vector component.
INTEGER(K4B) :: new,j,hgt
if (length < lenran) RETURN          Simply return if enough space is already al-
hgt=hg                                located.
    The following lines check that kind value K4B is in fact a 32-bit integer with the usual properties
    that we expect it to have (under negation and wrap-around addition). If all of these tests are
    satisfied, then the routines that use this module are portable, even though they go beyond
    Fortran 90's integer model.
if (hg /= 2147483647) call nrerror('ran_init: arith assumpt 1 fails')
if (hgng >= 0) call nrerror('ran_init: arith assumpt 2 fails')

    mran => ranseeds(2:,4)
    nran => ranseeds(2:,5)
    ranv = nran

```

```

end if
lenran=length
END SUBROUTINE ran_init

```

f90 `hgt=hg ... if (hgt+1 /= hgng)` Bit of dirty laundry here! We are testing whether the most positive integer `hg` wraps around to the most negative integer `hgng` when 1 is added to it. We can't just write `hg+1`, since some compilers will evaluate this at compile time and return an overflow error message. If your compiler sees through the charade of the temporary variable `hgt`, you'll have to find another way to trick it.

`amm=nearest(1.0_sp,-1.0_sp)/hgng...` Logically, `amm` should be a parameter; but the `nearest` intrinsic is trouble-prone in the initialization expression for a parameter (named constant), so we compute this at run time. We then check that `amm`, when multiplied by the largest possible negative integer, does not equal or exceed unity. (Our random deviates are guaranteed never to equal zero or unity exactly.)

You might wonder why `amm` is negative, and why we multiply it by negative integers to get positive random deviates. The answer, which will become manifest in the random generators given below, is that we want to use the fast `not` operation on integers to convert them to nonzero values of all one sign. This is possible if the conversion is to negative values, since `not(i)` is negative for all nonnegative `i`. If the conversion were to positive values, we would have problems both with zero (its sign bit is already positive) and `hgng` (since `not(hgng)` is generally zero).

```

iran0=ranseeds(1,1) ...
iran => ranseeds(2:,1)...

```

The initial state information is stored in `ranseeds`, a two-dimensional array whose column (second) index ranges from 1 to 5 over the state variables. `ranseeds(1, :)` is reserved for scalar random generators, while `ranseeds(2: , :)` is for vector-parallel generators. The `ranseeds` array is made available to vector generators through the pointers `iran`, `jran`, `kran`, `mran`, and `nran`. The corresponding scalar values, `iran0`, ..., `nran0` are simply global variables, not pointers, because the overhead of addressing a scalar through a pointer is often too great. (We will have to copy these scalar values back into `ranseeds` when it, rarely, needs to be addressed as an array.)

`call ran_hash(...)` Unique, and random, initial state information is obtained by putting a user-settable “sequence number” into `iran`, a component number into `jran`, and hashing this pair. Then `jran` and `kran` are hashed, `kran` and `mran` are hashed, and so forth.

```

SUBROUTINE ran_deallocate
  User interface to release the workspace used by the random number routines.
  if (lenran > 0) then
    deallocate(ranseeds,ranv)
    nullify(ranseeds,ranv,iran,jran,kran,mran,nran)
    lenran = 0
  end if
END SUBROUTINE ran_deallocate

```

The above routine is supplied as a user interface for deallocating all the state space storage.

```

SUBROUTINE ran_seed(sequence,size,put,get)
IMPLICIT NONE
INTEGER, OPTIONAL, INTENT(IN) :: sequence
INTEGER, OPTIONAL, INTENT(OUT) :: size
INTEGER, DIMENSION(:), OPTIONAL, INTENT(IN) :: put
INTEGER, DIMENSION(:), OPTIONAL, INTENT(OUT) :: get
    User interface for seeding the random number routines. Syntax is exactly like Fortran 90's
    random_seed routine, with one additional argument keyword: sequence, set to any integer
    value, causes an immediate new initialization, seeded by that integer.
if (present(size)) then
    size=5*lenran
else if (present(put)) then
    if (lenran == 0) RETURN
    ranseeds=reshape(put,shape(ranseeds))
    where (ranseeds(:,1:3) < 0) ranseeds(:,1:3)=not(ranseeds(:,1:3))
    Enforce nonnegativity and nonzero conditions on any user-supplied seeds.
    where (ranseeds(:,4:5) == 0) ranseeds(:,4:5)=1
    iran0=ranseeds(1,1)
    jran0=ranseeds(1,2)
    kran0=ranseeds(1,3)
    mran0=ranseeds(1,4)
    nran0=ranseeds(1,5)
else if (present(get)) then
    if (lenran == 0) RETURN
    ranseeds(1,1:5)=(/ iran0,jran0,kran0,mran0,nran0 /)
    get=reshape(ranseeds,shape(get))
else if (present(sequence)) then
    call ran_deallocate
    seq=sequence
end if
END SUBROUTINE ran_seed

```

```

ranseeds=reshape(put,shape(ranseeds)) ...
get=reshape(ranseeds,shape(get))

```

Fortran 90's convention is that random state space is a one-dimensional array, so we map to this on both the get and put keywords.

```

iran0=...jran0=...kran0=...
ranseeds(1,1:5)=(/ iran0,jran0,kran0,mran0,nran0 /)

```

It's much more convenient to set a vector from a bunch of scalars than the other way around.

```

SUBROUTINE ran_hash_s(il,ir)

```

are *not* a Marsaglia shift sequence, though they resemble one. Instead, they implement a fast, nonlinear function on *ir* that we use as the “S-box” in a DES-like hashing algorithm. (See Volume 1, §7.5.) The triplet (5, −16, 9) is *not* chosen to give a full period Marsaglia sequence — it doesn’t. Instead it is chosen as being particularly good at separating in Hamming distance (i.e., number of nonidentical bits) two initially close values of *ir* (e.g., differing by only one bit). The large integer constants are chosen by a similar criterion. Note that the wrap-around of addition without generating an overflow error condition, which was tested in *ran_init*, is relied upon here.

```

This is the simplest, and fastest, of the generators provided. It combines a subtractive Fibonacci generator (Number 6 in ref. [1], and one of the generators in Marsaglia and Zaman's `mzran`) with a Marsaglia shift sequence. On typical machines it is only 20% or so faster than `ran1`, however; so we recommend the latter preferentially. While we know of no weakness in `ran0`, we are not offering a prize for finding a weakness. `ran0` does have the feature, useful if you have a machine with nonstandard arithmetic, that it does not go beyond Fortran 90's assumed integer model.

Note that `ran0_s` and `ran0_v` are overloaded by the module `nr` onto the single name `ran0` (and similarly for the routines below).

* * *

```

SUBROUTINE ran1_s(harvest)
USE nrtype
USE ran_state, ONLY: K4B,amm,lenran,ran_init, &
iran0,jran0,kran0,nran0,mran0,rans
IMPLICIT NONE
REAL(SP), INTENT(OUT) :: harvest

```

Lagged Fibonacci generator combined with two Marsaglia shift sequences. On output, returns as `harvest` a uniform random deviate between 0.0 and 1.0 (exclusive of the endpoint values). This generator has the same calling and initialization conventions as Fortran 90's `random_number` routine. Use `ran_seed` to initialize or reinitialize to a particular sequence. The period of this generator is about 8.5×10^{37} , and it fully vectorizes. Validity of the integer model assumed by this generator is tested at initialization.

```

The routine `ran1` combines *three* fast generators: the two used in `ran0`, plus an additional (different) Marsaglia shift sequence. The last generator is combined via an addition that can wrap-around.

We think that, within the limits of its floating-point precision, `ran1` provides perfect random numbers. We will pay \$1000 to the first reader who convinces us otherwise (by exhibiting a statistical test that `ran1` fails in a nontrivial way, excluding the ordinary limitations of a floating-point representation).

```

ran2, for use by readers whose caution is extreme, also combines three generators. The difference from ran1 is that each generator is based on a completely different method from the other two. The third generator, in this case, is a linear congruential generator, modulo 2^{32} . This generator relies extensively on wrap-around addition (which is automatically tested at initialization). On machines with fast arithmetic, ran2 is on the order of only 20% slower than ran1. We offer a \$1000 bounty on ran2, with the same terms as for ran1, above.

★ ★ ★

```

SUBROUTINE expdev_s(harvest)
USE nrtype
USE nr, ONLY : ran1
IMPLICIT NONE
REAL(SP), INTENT(OUT) :: harvest
  Returns in harvest an exponentially distributed, positive, random deviate of unit mean,
  using ran1 as the source of uniform deviates.
REAL(SP) :: dum
call ran1(dum)
harvest=-log(dum)
END SUBROUTINE expdev_s
  We use the fact that ran1 never returns exactly 0 or 1.

```

```

SUBROUTINE expdev_v(harvest)
USE nrtype
USE nr, ONLY : ran1
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(OUT) :: harvest
REAL(SP), DIMENSION(size(harvest)) :: dum
call ran1(dum)
harvest=-log(dum)
END SUBROUTINE expdev_v

```

f90 call ran1(dum) The only noteworthy thing about this line is its simplicity: Once all the machinery is in place, the random number generators are self-initializing (to the sequence defined by seq = 0), and (via overloading) usable with both scalar and vector arguments.

★ ★ ★

```

SUBROUTINE gasdev_s(harvest)

if (n /= last_allocated) ... We make the assumption that, in most cases, the size of harvest will not change between successive calls. Therefore, if it *does* change, we don't try to save the previously generated deviates that, half the time, will be around. If your use has rapidly varying sizes (or, even worse, calls alternating between two different sizes), you should remedy this inefficiency in the obvious way.

call array_copy(pack(v1(ng:n),mask(ng:n)),v1(ng:),nn,m) This is a variant of the pack-unpack method (see note to `factr1`, p. 1087). Different here is that we don't care which random deviates end up in which component. Thus, we can simply keep packing successful returns into `v1` and `v2` until they are full.

Note also the use of `array_copy`, since we don't know in advance the length of the array returned by `pack`.

* * *

```

FUNCTION gamdev(ia)
USE nrtype; USE nrutil, ONLY : assert
USE nr, ONLY : ran1
IMPLICIT NONE
INTEGER(I4B), INTENT(IN) :: ia
REAL(SP) :: gamdev

```

Returns a deviate distributed as a gamma distribution of integer order `ia`, i.e., a waiting time to the `ia`th event in a Poisson process of unit mean, using `ran1` as the source of uniform deviates.

```

REAL(SP) :: am,e,h,s,x,y,v(2),arr(5)
call assert(ia >= 1, 'gamdev arg')
if (ia < 6) then

```

Use direct method, adding waiting times.

```

      call ran1(arr(1:ia))
      x=-log(product(arr(1:ia)))
else
      do
        call ran1(v)
        v(2)=2.0_sp*v(2)-1.0_sp
        if (dot_product(v,v) > 1.0) cycle

        x=s*y+am
        if (x <= 0.0) cycle
        e=(1.0_sp+y**2)*exp(am*log(x/am)-s*y)
        call ran1(h)
        if (h <= e) exit
      end do
end if
gamdev=x
END FUNCTION gamdev

```

Use rejection method.

These three lines generate the tangent of a random angle, i.e., are equivalent to $y = \tan(\pi \text{ran}(\text{idum}))$.

We decide whether to reject x:
Reject in region of zero probability.
Ratio of probability function to comparison function.
Reject on basis of a second uniform deviate.

$x = -\log(\text{product}(\text{arr}(1:\text{ia})))$ Why take the log of the product instead of the sum of the logs? Because log is assumed to be slower than multiply.

We don't have vector versions of the less commonly used deviate generators, gamdev, poidev, and bnlddev.

★ ★ ★

```

FUNCTION poidev(xm)
USE nrtype
USE nr, ONLY : gammaln, ran1
IMPLICIT NONE
REAL(SP), INTENT(IN) :: xm
REAL(SP) :: poidev

```

Returns as a floating-point number an integer value that is a random deviate drawn from a Poisson distribution of mean xm, using ran1 as a source of uniform random deviates.

```

REAL(SP) :: em, harvest, t, y
REAL(SP), SAVE :: alxm, g, oldm = -1.0_sp, sq

```

oldm is a flag for whether xm has changed since last call.

```

if (xm < 12.0) then
  if (xm /= oldm) then
    oldm=xm
    g=exp(-xm)
  end if
  em=-1
  t=1.0
  do
    em=em+1.0_sp
    call ran1(harvest)

    if (t <= g) exit
  end do
else
  if (xm /= oldm) then
    oldm=xm
    sq=sqrt(2.0_sp*xm)
    alxm=log(xm)
    g=xm*alxm-gammaln(xm+1.0_sp)
  end if
  do

```

Use direct method.

If xm is new, compute the exponential.

Instead of adding exponential deviates it is equivalent to multiply uniform deviates. We never actually have to take the log; merely compare to the pre-computed exponential.

Use rejection method.

If xm has changed since the last call, then pre-compute some functions that occur below.

The function gammaln is the natural log of the gamma function, as given in §6.1.

```

do
    call ran1(harvest)
    y=tan(PI*harvest)
    em=sq*y+xm
    if (em >= 0.0) exit
end do
em=int(em)
t=0.9_sp*(1.0_sp+y**2)*exp(em*alxm-gammln(em+1.0_sp)-g)
    The ratio of the desired distribution to the comparison function; we accept or reject
    by comparing it to another uniform deviate. The factor 0.9 is chosen so that t never
    exceeds 1.
    call ran1(harvest)
    if (harvest <= t) exit
end do
end if
poidev=em
END FUNCTION poidev

```

y is a deviate from a Lorentzian comparison function.
em is y, shifted and scaled.
Reject if in regime of zero probability.

The trick for integer-valued distributions.

* * *

```

FUNCTION bnldev(pp,n)
USE nrtype
USE nr, ONLY : gammln,ran1
IMPLICIT NONE
REAL(SP), INTENT(IN) :: pp
INTEGER(I4B), INTENT(IN) :: n
REAL(SP) :: bnldev
    Returns as a floating-point number an integer value that is a random deviate drawn from a
    binomial distribution of n trials each of probability pp, using ran1 as a source of uniform
    random deviates.
INTEGER(I4B) :: j
INTEGER(I4B), SAVE :: nold=-1

f90 The routines `psdes` and `psdes_safe` both perform *exactly* the same hashing as was done by the Fortran 77 routine `psdes`. The difference is that `psdes` makes assumptions about arithmetic that go beyond the strict Fortran 90 model, while `psdes_safe` makes no such assumptions. The disadvantage of `psdes_safe` is that it is significantly slower, performing most of its arithmetic in double-precision reals that are then converted to integers with Fortran 90's modulo intrinsic.

In fact the nonsafe version, `psdes`, works fine on almost all machines and compilers that we have tried. There is a reason for this: Our assumed integer model is the same as the C language unsigned `int`, and virtually all modern computers and compilers have a lot of C hidden inside. If `psdes` and `psdes_safe` produce identical output on your system for any hundred or so different input values, you can be quite confident about using the faster version exclusively.

At the other end of things, note that in the very unlikely case that your system fails on the `ran_hash` routine in the `ran_state` module (you will have learned this from error messages generated by `ran_init`), you can substitute `psdes_safe` for `ran_hash`: They are plug-compatible.

```

SUBROUTINE psdes_s(lword,rword)

```

As given, ran3 uses the ran_hash function in the module ran_state as its DES surrogate. That function is sufficiently fast to make ran3 only about a factor of 2 slower than our baseline recommended generator ran1. The slower routine psdes and (even slower) psdes_safe are plug-compatible with ran_hash, and could be substituted for it in this routine.

END INTERFACE
REAL(SP), PARAMETER :: ALPH=1.5_sp,TINY=1.0e-30_sp
INTEGER(I4B), PARAMETER :: MXDIM=10,NDMX=50

```

Performs Monte Carlo integration of a user-supplied d -dimensional function `func` over a rectangular volume specified by `region`, a vector of length $2d$ consisting of d "lower left" coordinates of the region followed by d "upper right" coordinates. The integration consists of `itmx` iterations, each with approximately `ncall` calls to the function. After each iteration the grid is refined; more than 5 or 10 iterations are rarely useful. The input flag `init` signals whether this call is a new start, or a subsequent call for additional iterations (see comments below). The input flag `nprn` (normally 0) controls the amount of diagnostic output. Returned answers are `tgral` (the best estimate of the integral), `sd` (its standard deviation), and `chi2a` (χ^2 per degree of freedom, an indicator of whether consistent results are being obtained). See text for further details.

REAL(SP), PARAMETER :: PFAC=0.1_sp,TINY=1.0e-30_sp,BIG=1.0e30_sp
INTEGER(I4B), PARAMETER :: MNPT=15,MNBS=60
  Monte Carlo samples a user-supplied ndim-dimensional function func in a rectangular
  volume specified by region, a 2×ndim vector consisting of ndim "lower-left" coordinates
  of the region followed by ndim "upper-right" coordinates. The function is sampled a total
  of npts times, at locations determined by the method of recursive stratified sampling. The
  mean value of the function in the region is returned as ave; an estimate of the statistical
  uncertainty of ave (square of standard deviation) is returned as var. The input parameter
  dith should normally be set to zero, but can be set to (e.g.) 0.1 if func's active region
  falls on the boundary of a power-of-2 subdivision of region.
  Parameters: PFAC is the fraction of remaining function evaluations used at each stage to
  explore the variance of func. At least MNPT function evaluations are performed in any
  terminal subregion; a subregion is further bisected only if at least MNBS function evaluations
  are available.

f90 The Fortran 90 version of this routine is much more straightforward than the Fortran 77 version, because Fortran 90 allows recursion. (In fact, this routine is modeled on the C version of *miser*, which was recursive from the start.)

Chapter B8. Sorting

Caution! If you are expecting to sort efficiently on a parallel machine, whether its parallelism is small-scale or massive, you almost certainly want to use library routines that are specific to your hardware.

We include in this chapter translations into Fortran 90 of the general purpose *serial* sorting routines that are in Volume 1, augmented by several new routines that give pedagogical demonstrations of how parallel sorts can be achieved with Fortran 90 parallel constructions and intrinsics. However, we intend the above word “pedagogical” to be taken seriously: these new, supposedly parallel, routines are *not* likely to be competitive with machine-specific library routines. Neither do they compete successfully on serial machines with the all-serial routines provided (namely `sort`, `sort2`, `sort3`, `indexx`, and `select`).

* * *

```
SUBROUTINE sort_pick(arr)
USE nrtype
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: arr
    Sorts an array arr into ascending numerical order, by straight insertion. arr is replaced
    on output by its sorted rearrangement.
INTEGER(I4B) :: i,j,n
REAL(SP) :: a
n=size(arr)
do j=2,n
    Pick out each element in turn.
    a=arr(j)
    do i=j-1,1,-1
        Look for the place to insert it.
        if (arr(i) <= a) exit
        arr(i+1)=arr(i)
    end do
    arr(i+1)=a
    Insert it.
end do
END SUBROUTINE sort_pick
```

Not only is `sort_pick` (renamed from Volume 1’s `picksrt`) *not parallelizable*, but also, even worse, it is an N^2 routine. It is meant to be invoked only for the most trivial sorting jobs, say, $N < 20$.

* * *

```

SUBROUTINE sort_shell(arr)
USE nrtype
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: arr
    Sorts an array arr into ascending numerical order by Shell's method (diminishing increment
    sort). arr is replaced on output by its sorted rearrangement.
INTEGER(I4B) :: i,j,inc,n
REAL(SP) :: v
n=size(arr)
inc=1
do
    Determine the starting increment.
    inc=3*inc+1
    if (inc > n) exit
end do
do
    Loop over the partial sorts.
    inc=inc/3
    do i=inc+1,n
        Outer loop of straight insertion.
        v=arr(i)
        j=i
        do
            Inner loop of straight insertion.
            if (arr(j-inc) <= v) exit
            arr(j)=arr(j-inc)
            j=j-inc
            if (j <= inc) exit
        end do
        arr(j)=v
    end do
    if (inc <= 1) exit
end do
END SUBROUTINE sort_shell

```

The routine `sort_shell` is renamed from Volume 1's `shell`. Shell's Method, a diminishing increment sort, is not directly parallelizable. However, one can write a fully parallel routine (though not an especially fast one — see remarks at beginning of this chapter) in much the same spirit:

```

SUBROUTINE sort_byreshape(arr)
USE nrtype; USE nrutil, ONLY : swap
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: arr
    Sort an array arr by bubble sorting a succession of reshaping into array slices. The method
    is similar to Shell sort, but allows parallelization within the vectorized masked swap calls.
REAL(SP), DIMENSION(:,:), ALLOCATABLE :: tab
REAL(SP), PARAMETER :: big=huge(arr)
INTEGER(I4B) :: inc,n,m
n=size(arr)
inc=1
do
    Find the largest increment that fits.
    inc=2*inc+1
    if (inc > n) exit
end do
do
    Loop over the different shapes for the reshaped
    array.
    inc=inc/2
    m=(n+inc-1)/inc
    allocate(tab(inc,m))
    Bubble sort all the rows in parallel.
    tab=reshape(arr, (/inc,m/), (/big/))
    ensures that fill elements stay at the
    end.
    do
        call swap(tab(:,1:m-1:2),tab(:,2:m:2), &
            tab(:,1:m-1:2)>tab(:,2:m:2))
        call swap(tab(:,2:m-1:2),tab(:,3:m:2), &
            tab(:,2:m-1:2)>tab(:,3:m:2))
    end do
end do

```

```

        if (all(tab(:,1:m-1) <= tab(:,2:m))) exit
    end do
    arr=reshape(tab,shape(arr))          Put the array back together for the next shape.
    deallocate(tab)
    if (inc <= 1) exit
end do
END SUBROUTINE sort_byreshape

```

The basic idea is to reshape the given one-dimensional array into a succession of two-dimensional arrays, starting with “tall and narrow” (many rows, few columns), and ending up with “short and wide” (many columns, few rows). At each stage we sort all the rows in parallel by a bubble sort, giving something close to Shell’s diminishing increments.

* * *

We now arrive at those routines, based on the Quicksort algorithm, that we actually intend for use with general N on serial machines:

```

SUBROUTINE sort(arr)
USE nrtype; USE nrutil, ONLY : swap,nrerror
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: arr
INTEGER(I4B), PARAMETER :: NN=15, NSTACK=50
    Sorts an array arr into ascending numerical order using the Quicksort algorithm. arr is
    replaced on output by its sorted rearrangement.
    Parameters: NN is the size of subarrays sorted by straight insertion and NSTACK is the
    required auxiliary storage.
REAL(SP) :: a
INTEGER(I4B) :: n,k,i,j,jstack,l,r
INTEGER(I4B), DIMENSION(NSTACK) :: istack
n=size(arr)
jstack=0
l=1
r=n
do
    if (r-l < NN) then
        Insertion sort when subarray small enough.
        do j=l+1,r
            a=arr(j)
            do i=j-1,l,-1
                if (arr(i) <= a) exit
                arr(i+1)=arr(i)
            end do
            arr(i+1)=a
        end do
        if (jstack == 0) RETURN
        r=istack(jstack)
        l=istack(jstack-1)
        jstack=jstack-2
    else
        Choose median of left, center, and right elements
        as partitioning element a. Also rearrange so
        that  $a(l) \leq a(l+1) \leq a(r)$ .
        k=(l+r)/2
        call swap(arr(k),arr(l+1))
        call swap(arr(l),arr(r),arr(l)>arr(r))
        call swap(arr(l+1),arr(r),arr(l+1)>arr(r))
        call swap(arr(l),arr(l+1),arr(l)>arr(l+1))
        i=l+1
        j=r
        a=arr(l+1)
        Partitioning element.
        Here is the meat.
        do
            Scan up to find element  $\geq a$ .
            i=i+1

```

```

        if (arr(i) >= a) exit
    end do
    do
        j=j-1
        if (arr(j) <= a) exit
    end do
    if (j < i) exit
    call swap(arr(i),arr(j))
end do
arr(l+1)=arr(j)
arr(j)=a
jstack=jstack+2
    Push pointers to larger subarray on stack; process smaller subarray immediately.
if (jstack > NSTACK) call nrerror('sort: NSTACK too small')
if (r-i+1 >= j-1) then
    istack(jstack)=r
    istack(jstack-1)=i
    r=j-1
else
    istack(jstack)=j-1
    istack(jstack-1)=l
    l=i
end if
end if
end do
END SUBROUTINE sort

```

f90 call swap(...) ... call swap(...) One might think twice about putting all these external function calls (to `nrutil` routines) in the inner loop of something as streamlined as a sort routine, but here they are executed only once for each partitioning.

call swap(arr(i),arr(j)) This call *is* in a loop, but not the innermost loop. Most modern machines are very fast at the “context changes” implied by subroutine calls and returns; but in a time-critical context you might code this swap in-line and see if there is any timing difference.

```

SUBROUTINE sort2(arr,slave)
USE nrtype; USE nrutil, ONLY : assert_eq
USE nr, ONLY : indexx
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: arr,slave
    Sorts an array arr into ascending order using Quicksort, while making the corresponding
    rearrangement of the same-size array slave. The sorting and rearrangement are performed
    by means of an index array.
INTEGER(I4B) :: ndum
INTEGER(I4B), DIMENSION(size(arr)) :: index
ndum=assert_eq(size(arr),size(slave),'sort2')
call indexx(arr,index)
arr=arr(index)
slave=slave(index)
END SUBROUTINE sort2

```

Make the index array.
Sort arr.
Rearrange slave.

* * *

A close surrogate for the Quicksort partition-exchange algorithm can be coded, parallelizable, by using Fortran 90's `pack` intrinsic. On real compilers, unfortunately, the resulting code is not very efficient as compared with (on serial machines) the tightness of `sort`'s inner loop, above, or (on parallel machines) supplied library sort routines. We illustrate the principle nevertheless in the following routine.

```

RECURSIVE SUBROUTINE sort_bypack(arr)
USE nrtype; USE nrutil, ONLY : array_copy, swap
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: arr
    Sort an array arr by recursively applying the Fortran 90 pack intrinsic. The method is
    similar to Quicksort, but this variant allows parallelization by the Fortran 90 compiler.
REAL(SP) :: a
INTEGER(I4B) :: n,k,nl,nerr
INTEGER(I4B), SAVE :: level=0
LOGICAL, DIMENSION(:), ALLOCATABLE, SAVE :: mask
REAL(SP), DIMENSION(:), ALLOCATABLE, SAVE :: temp
n=size(arr)
if (n <= 1) RETURN
k=(1+n)/2
call swap(arr(1),arr(k),arr(1)>arr(k))           Pivot element is median of first, middle,
call swap(arr(k),arr(n),arr(k)>arr(n))           and last.
call swap(arr(1),arr(k),arr(1)>arr(k))
if (n <= 3) RETURN
level=level+1
if (level == 1) allocate(mask(n),temp(n))       Keep track of recursion level to avoid al-
                                                location overhead.
a=arr(k)
mask(1:n) = (arr <= a)                          Which elements move to left?
mask(k) = .false.
call array_copy(pack(arr,mask(1:n)),temp,nl,nerr)   Move them.
mask(k) = .true.
temp(nl+2:n)=pack(arr,.not. mask(1:n))           Move others to right.
temp(nl+1)=a
arr=temp(1:n)
call sort_bypack(arr(1:nl))                      And recurse.
call sort_bypack(arr(nl+2:n))
if (level == 1) deallocate(mask,temp)
level=level-1
END SUBROUTINE sort_bypack

```

* * *

The following routine, `sort_heap`, is renamed from Volume 1's `hpsort`.

```

SUBROUTINE sort_heap(arr)
USE nrtype
USE nrutil, ONLY : swap
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: arr
    Sorts an array arr into ascending numerical order using the Heapsort algorithm. arr is
    replaced on output by its sorted rearrangement.
INTEGER(I4B) :: i,n
n=size(arr)
do i=n/2,1,-1
    The index i, which here determines the "left" range of the sift-down, i.e., the element to
    be sifted down, is decremented from n/2 down to 1 during the "hiring" (heap creation)
    phase.
    call sift_down(i,n)
end do
do i=n,2,-1
    Here the "right" range of the sift-down is decremented from n-1 down to 1 during the
    "retirement-and-promotion" (heap selection) phase.
    call swap(arr(1),arr(i))           Clear a space at the end of the array, and

* * *

Another opportunity provided by Fortran 90 for a fully parallelizable sort, at least pedagogically, is to use the language's allowed access to the actual floating-point representation and to code a radix sort [1] on its bits. This is *not* efficient, but it illustrates some Fortran 90 language features perhaps worthy of study for other applications.

```

      SUBROUTINE sort_radix(arr)
      USE nrtyp; USE nrutil, ONLY : array_copy,nrerror
      IMPLICIT NONE
      REAL(SP), DIMENSION(:), INTENT(INOUT) :: arr
      Sort an array arr by radix sort on its bits.
      INTEGER(I4B), DIMENSION(size(arr)) :: narr,temp
      LOGICAL, DIMENSION(size(arr)) :: msk
      INTEGER(I4B) :: k,negm,ib,ia,n,nl,nerr
      Because we are going to transfer reals to integers, we must check that the number of bits
      is the same in each:
      ib=bit_size(narr)
      ia=ceiling(log(real(maxexponent(arr)-minexponent(arr),sp))/log(2.0_sp)) &
      + digits(arr)
      if (ib /= ia) call nrerror('sort_radix: bit sizes not compatible')
      negm=not(ishftc(1,-1))                                Mask for all bits except sign bit.
      n=size(arr)
      narr=transfer(arr,narr,n)
      where (btest(narr,ib-1)) narr=ieor(narr,negm)          Flip all bits on neg. numbers.
      do k=0,ib-2
          Work from low- to high-order bits, and partition the array according to the value of the
          bit.
          msk=btest(narr,k)
          call array_copy(pack(narr,.not. msk),temp,nl,nerr)

★ ★ ★

Just as in the case of `sort`, where an approximation of the underlying Quicksort partition-exchange algorithm can be captured with the Fortran 90 `pack` intrinsic, the same can be done with `indexx`. As before, although it is in principle parallelizable by the compiler, it is likely not competitive with library routines.

```

RECURSIVE SUBROUTINE index_bypack(arr,index,partial)
USE nrtype; USE nrutil, ONLY : array_copy,arth,assert_eq
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: arr
INTEGER(I4B), DIMENSION(:), INTENT(OUT) :: index
INTEGER, OPTIONAL, INTENT(IN) :: partial
    Indexes an array arr, i.e., outputs the array index of length  $N$  such that arr(index(j))
    is in ascending order for  $j = 1, 2, \dots, N$ . The method is to apply recursively the Fortran
    90 pack intrinsic. This is similar to Quicksort, but allows parallelization by the Fortran 90
    compiler. partial is an optional argument that is used only internally on the recursive calls.

* * *

The following routine, `select_inplace`, is renamed from Volume 1's `selip`.

```

FUNCTION select_inplace(k,arr)
USE nrtype
USE nr, ONLY : select
IMPLICIT NONE
INTEGER(I4B), INTENT(IN) :: k
REAL(SP), DIMENSION(:), INTENT(IN) :: arr
REAL(SP) :: select_inplace
    Returns the kth smallest value in the array arr, without altering the input array. In Fortran
    90's assumed memory-rich environment, we just call select in scratch space.
REAL(SP), DIMENSION(size(arr)) :: tarr
tarr=arr
select_inplace=select(k,tarr)
END FUNCTION select_inplace

```

F₉₀ Volume 1's `selip` routine uses an entirely different algorithm, for the purpose of avoiding any additional memory allocation beyond that of the input array. Fortran 90 presumes a richer memory environment, so `select_inplace` simply does the obvious (destructive) selection in scratch space. You can of course use the old `selip` if your in-core or in-cache memory is at a premium.

```

FUNCTION select_bypack(k,arr)

f90 CHARACTER(1), DIMENSION(ISCR,JSCR) :: scr In Fortran 90, the length of variables of type character should be declared as CHARACTER(1) or CHARACTER(len=1) (for a variable of length 1), rather than the older form CHARACTER*1. While the older form is still legal syntax, the newer one is more consistent with the syntax of other type declarations. (For variables of length 1, you can actually omit the length specifier entirely, and just say CHARACTER.)

    Very unusual — can occur only for complex roots. Try a different starting guess for the root.
END SUBROUTINE laguer

```

Loop over iterations up to allowed maximum.

Efficient computation of the polynomial and its first two derivatives.

f stores $P''/2$.

Estimate of roundoff in evaluating polynomial.

We are on the root.

The generic case: Use Laguerre's formula.

Converged.

Every so often we take a fractional step, to break any limit cycle (itself a rare occurrence).

f90 $b(m+1:1:-1)=\text{poly_term} \dots f=\text{poly}(x,d(2:m))$ The `poly_term` function in `nrutil` tabulates the partial sums of a polynomial, while `poly` evaluates the polynomial at x . In this example, we use `poly_term` on the coefficient array in reverse order, so that the value of the polynomial ends up in `b(1)` and the value of its first derivative in `d(1)`.

$dx=\exp(\text{cmplx}(\log(1.0_sp+abx),\text{iter},\text{kind}=spc))$ The intrinsic function `cmplx` returns a quantity of type default complex unless the `kind` argument is present. To facilitate converting our routines from single to double precision, we always include the `kind` argument explicitly so that when you redefine `spc` in `nrtype` to be double-precision complex the conversions are carried out correctly.

REAL(SP), PARAMETER :: ALF=1.0e-4_sp,TOLX=epsilon(x)

```

Given an N -dimensional point $xold$, the value of the function and gradient there, $fold$ and g , and a direction p , finds a new point x along the direction p from $xold$ where the function $func$ has decreased “sufficiently.” $xold$, g , p , and x are all arrays of length N . The new function value is returned in f . $stpmax$ is an input quantity that limits the length of the steps so that you do not try to evaluate the function in regions where it is undefined or subject to overflow. p is usually the Newton direction. The output quantity $check$ is false on a normal exit. It is true when x is too close to $xold$. In a minimization algorithm, this usually signals convergence and can be ignored. However, in a zero-finding algorithm the calling program should check whether the convergence is spurious.

Parameters: ALF ensures sufficient decrease in function value; $TOLX$ is the convergence criterion on Δx .

```

f90 **USE fminln** Here we have an example of how to pass an array `fvec` to a function `fmin` without making it an argument of `fmin`. In the language of §21.5, we are using Method 2: We define a pointer `fmin_fvecp` in the module `fminln`:

```
REAL(SP), DIMENSION(:), POINTER :: fmin_fvecp
```

`fvec` itself is declared as an automatic array of the appropriate size in `newt`:

```
REAL(SP), DIMENSION(size(x)), TARGET :: fvec
```

On entry into `newt`, the pointer is associated:

```
fmin_fvecp=>fvec
```

The pointer is then used in `fmin` as a synonym for `fvec`. If you are sufficiently paranoid, you can test whether `fmin_fvecp` has in fact been associated on entry into `fmin`. Heeding our admonition always to deallocate memory when it no longer is needed, you may ask where the deallocation takes place in this example. Answer: On exit from `newt`, the automatic array `fvec` is automatically freed.

The Method 1 way of setting up this task is to declare an allocatable array in the module:

```
REAL(SP), DIMENSION(:), ALLOCATABLE :: fvec
```

On entry into `newt` we allocate it appropriately:

```
allocate(fvec,size(x))
```

and it can now be used in both `newt` and `fmin`. Of course, we must remember to deallocate explicitly `fvec` on exit from `newt`. If we forget, all kinds of bad things would happen on a second call to `newt`. The status of `fvec` on the first return from `newt` becomes undefined. The status cannot be tested with `if(allocated(...))`, and `fvec` may not be referenced in any way. If we tried to guard against this by adding the `SAVE` attribute to the declaration of `fvec`, then we would generate an error from trying to allocate an already-allocated array.

```

USE fminln See discussion for newt on p. 1197.

qt(k:n,:)=...outerprod...matmul Another example of the coding of equation (22.1.6).

where (lower_triangle(n,n))... The lower_triangle function in nrutil returns a lower triangular logical mask. As used here, the mask is true everywhere in the lower triangle of an $n \times n$ matrix, excluding the diagonal. An optional integer argument extra allows additional diagonals to be set to true. With extra=1 the lower triangle including the diagonal would be true.

call put_diag(d(:),r(:,:)) This subroutine in nrutil sets the diagonal values of the matrix r to the values of the vector d. It is overloaded so that d could be a scalar, in which case the scalar value would be broadcast onto the diagonal of r.

Chapter B10. Minimization or Maximization of Functions

```

SUBROUTINE mnbrak(ax,bx,cx,fa,fb,fc,func)
USE nrtype; USE nrutil, ONLY : swap

REAL(SP), PARAMETER :: TINY=1.0e-10
    Minimization of the function func in  $N$  dimensions by the downhill simplex method of
    Nelder and Mead. The  $(N + 1) \times N$  matrix p is input. Its  $N + 1$  rows are  $N$ -dimensional
    vectors that are the vertices of the starting simplex. Also input is the vector y of length
     $N + 1$ , whose components must be preinitialized to the values of func evaluated at the
     $N + 1$  vertices (rows) of p; and ftol the fractional convergence tolerance to be achieved
    in the function value (n.b.!). On output, p and y will have been reset to  $N + 1$  new points
    all within ftol of a minimum function value, and iter gives the number of function
    evaluations taken.
    Parameters: The maximum allowed number of function evaluations, and a small number.
INTEGER(I4B) :: ihi,ndim

f90 The only action taken by the subroutine `amoeba` is to call the internal subroutine `amoeba_private`. Why this structure? The reason has to do with meeting the twin goals of data hiding (especially for “safe” scope of variables) and program readability. The situation is this: Logically, `amoeba` does most of the calculating, but calls an internal subroutine `amotry` at several different points, with several values of the parameter `fac`. However, `fac` is not the only piece of data that must be shared with `amotry`; the latter also needs access to several shared variables (`ihi`, `ndim`, `psum`) and arguments of `amoeba` (`p`, `y`, `func`).

The obvious (but not best) way of coding this would be to put the computational guts in `amoeba`, with `amotry` as the sole internal subprogram. Assuming that `fac` is passed as an argument to `amotry` (it being the parameter that is being rapidly altered), one must decide whether to pass all the other quantities to `amotry` (i) as additional arguments (as is done in the Fortran 77 version), or (ii) “automatically,” i.e., doing nothing except using the fact that an internal subprogram has automatic access to all of its host’s entities. Each of these choices has strong disadvantages. Choice (i) is inefficient (all those arguments) and also obscures the fact that `fac` is the primary changing argument. Choice (ii) makes the program extremely difficult to read, because it wouldn’t be obvious without careful cross-comparison of the routines *which* variables in `amoeba` are actually global variables that are used by `amotry`.

Choice (ii) is also “unsafe scoping” because it gives a nontrivially complicated internal subprogram, `amotry`, access to all the variables in its host. A common and difficult-to-find bug is the accidental alteration of a variable that one “thought”

was local, but is actually shared. (Simple variables like *i*, *j*, and *n* are the most common culprits.)

We are therefore led to reject both choice (i) and choice (ii) in favor of a structure previously described in the subsection on Scope, Visibility, and Data Hiding in §21.5. The guts of *amoeba* are put in *amoeba_private*, a *sister routine* to *amotry*. These two siblings have mutually private name spaces. However, any variables that they need to share (including the top-level arguments of *amoeba*) are declared as variables in the enclosing *amoeba* routine. The presence of these “global variables” serves as a warning flag to the reader that data are shared between routines.

An alternative attractive way of coding the above situation would be to use a module containing *amoeba* and *amotry*. Everything would be declared private except the name *amoeba*. The global variables would be at the top level, and the arguments of *amoeba* that need to be passed to *amotry* would be handled by pointers among the global variables. Unfortunately, Fortran 90 does not support pointers to functions. Sigh!

`ilo=iminloc...ihi=imaxloc...` See discussion of these functions on p. 1017.

`call swap(y(1)...call swap(p(1,:))...` Here the *swap* routine in *nrutil* is called once with a scalar argument and once with a vector argument. Inside *nrutil* scalar and vector versions have been overloaded onto the single name *swap*, hiding all the implementation details from the calling routine.

```

f90 `USE f1dim_mod` At first sight this situation is like the one involving `USE fminln` in `newt` on p. 1197: We want to pass arrays p and xi from `linmin` to `f1dim` without having them be arguments of `f1dim`. If you recall the discussion in §21.5 and on p. 1197, there are two ways of effecting this: via pointers or via allocatable arrays. There is an important difference here, however. The arrays p and xi are themselves arguments of `linmin`, and so cannot be allocatable arrays in the module. If we did want to use allocatable arrays in the module, we would have to copy p and xi into them. The pointer implementation is much more elegant, since no unnecessary copying is required. The construction here is identical to the one in `fminln` and `newt`, except that p and xi are arguments instead of automatic arrays.

Done. Solution found. Return with the good news.

Locate a pivot element (phase two). Objective function is unbounded. Report and return.

Exchange a left- and a right-hand variable, update lists of left- and right-hand variables, and return for another iteration.

No possible pivots. Return with message.

We have a degeneracy.

f90 `main_procedure: do` The routine `simplx` makes extensive use of named do-loops to control the program flow. The various `exit` statements have the names of the do-loops attached to them so we can easily tell where control is being transferred to. We believe that it is almost never necessary to use `goto` statements: Code will always be clearer with well-constructed block structures.

`phase1a: do...end do phase1a` This is not a real do-loop: It is executed only once, as you can see from the unconditional `exit` before the `end do`. We use this construction to define a block of code that is traversed once but that has several possible exit points.

```
where (spread(l3(1:m12-m1),2,n+1) == 1) &
a(m1+2:m12+1,1:n+1)=-a(m1+2:m12+1,1:n+1)
```

These lines are equivalent to

```
do i=m1+1,m12
  if (l3(i-m1) == 1) a(i+1,1:n+1)=-a(i+1,1:n+1)
end do
```

```

Find the city before *n*(1) ...
... and the city after *n*(2).
Find coordinates for the four cities involved.

Calculate cost of disconnecting the segment
at both ends and reconnecting in the op-
posite order.

This many cities must be swapped to effect
the reversal.
Start at the ends of the segment and swap
pairs of cities, moving toward the center.

Find the city following *n*(3) ...
... and the one preceding *n*(1) ...
... and the one following *n*(2).
Determine coordinates for the six cities in-
volved.
Calculate the cost of disconnecting the path
segment from *n*(1) to *n*(2), opening a
space between *n*(3) and *n*(4), connect-
ing the segment in the space, and connect-
ing *n*(5) to *n*(6).

```
INTEGER(I4B), DIMENSION(:), INTENT(INOUT) :: iorder
INTEGER(I4B), DIMENSION(:), INTENT(IN) :: n
```

This routine does the actual path transport, once metrop has approved. `iorder` is an input array giving the present itinerary. The array `n` has as its six elements the beginning `n(1)` and end `n(2)` of the path to be transported, the adjacent cities `n(3)` and `n(4)` between which the path is to be placed, and the cities `n(5)` and `n(6)` that precede and follow the path. `n(4)`, `n(5)`, and `n(6)` are calculated by subroutine `trncst`. On output, `iorder` is modified to reflect the movement of the path segment.

```

INTEGER(I4B), PARAMETER :: NMAX=200
Minimization of the  $N$ -dimensional function func by simulated annealing combined with the
downhill simplex method of Nelder and Mead. The  $(N+1) \times N$  matrix p is input. Its  $N+1$ 
rows are  $N$ -dimensional vectors that are the vertices of the starting simplex. Also input is
the vector y of length  $N+1$ , whose components must be preinitialized to the values of func
evaluated at the  $N+1$  vertices (rows) of p; ftol, the fractional convergence tolerance to be
achieved in the function value for an early return; iter, and temptr. The routine makes
iter function evaluations at an annealing temperature temptr, then returns. You should
then decrease temptr according to your annealing schedule, reset iter, and call the routine
again (leaving other arguments unaltered between calls). If iter is returned with a positive
value, then early convergence and return occurred. If you initialize yb to a very large value
on the first call, then yb and pb (an array of length  $N$ ) will subsequently return the best
function value and point ever encountered (even if it is no longer a point in the simplex).

    Begin a new iteration. First extrapolate by a factor -1 through the face of the simplex
    across from the high point, i.e., reflect the simplex from the high point.
    ytry=amotsa(-1.0_sp)
    iter=iter-1
    if (ytry <= ylo) then
      ytry=amotsa(2.0_sp)
      iter=iter-1
      Gives a result better than the best point, so
      try an additional extrapolation by a factor
      of 2.
    else if (ytry >= ynhi) then
      ysave=yhi
      ytry=amotsa(0.5_sp)
      iter=iter-1
      The reflected point is worse than the second-
      highest, so look for an intermediate lower
      point, i.e., do a one-dimensional contrac-
      tion.
      if (ytry >= ysave) then
        Can't seem to get rid of that high point. Better contract around the lowest
        (best) point.

As discussed in Volume 1, `jacobi` is generally not competitive with `tqli` in terms of efficiency. However, `jacobi` can be parallelized whereas `tqli` uses an intrinsically serial algorithm. The version of `jacobi` implemented here is likely to be adequate for a small-scale parallel (SSP) machine, but is probably still not competitive with `tqli`. For a massively multiprocessor (MMP) machine, the order of the rotations needs to be chosen in a more complicated pattern than here so that the rotations can be executed in parallel. In this case the Jacobi algorithm may well turn out to be the method of choice. Parallel replacements for `tqli` based on a divide and conquer algorithm have also been proposed. See the discussion after `tqli` on p. 1229.

`call unit_matrix...b(:)=get_diag...` These routines in `nrutil` both require access to the diagonal of a matrix, an operation that is not conveniently provided for in Fortran 90. We have split them off into `nrutil` in case your compiler provides parallel library routines so you can replace our standard versions.

`sm=sum(abs(a),mask=upper_triangle(n,n))` The `upper_triangle` function in `nrutil` returns an upper triangular logical mask. As used here, the mask is true everywhere in the upper triangle of an $n \times n$ matrix, excluding the diagonal. An optional integer argument `extra` allows additional diagonals to be set to true. With `extra=1` the upper triangle including the diagonal would be true. By using the mask, we can conveniently sum over the desired matrix elements in parallel.

`SUBROUTINE jrotate(a1,a2)` This internal subroutine also uses the values of `s` and `tau` from the calling subroutine `jacobi`. Variables in the calling routine are visible to an internal subprogram, but you should be circumspect in making use of this fact. It is easy to overwrite a value in the calling program inadvertently, and it is

often difficult to figure out the logic of an internal routine if not all its variables are declared explicitly. However, `jrotate` is so simple that there is no danger here.

```

Now **h** is equation (11.2.4).
 Store **u** in the *i*th row of **a**.
 Store **u/H** in *i*th column of **a**.
 Store elements of **p** in temporarily unused elements of **e**.
 Form **K**, equation (11.2.11).
 Reduce **a**, equation (11.2.13).
 Begin accumulation of transformation matrices.
 Reset row and column of **a** to identity matrix for next iteration.

This routine gives a nice example of the usefulness of optional arguments. The routine is written under the assumption that usually you will want to find both eigenvalues and eigenvectors. In this case you just supply the arguments **a**, **d**, and **e**. If, however, you want only eigenvalues, you supply the additional logical argument **novectors** with the value **.true.**. The routine then skips the unnecessary computations. Supplying **novectors** with the value **.false.** has the same effect as omitting it.

SUBROUTINE tqli(d,e,z)
USE nrtype; USE nrutil, ONLY : assert_eq,nrerror
USE nr, ONLY : pythag
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: d,e
REAL(SP), DIMENSION(:,:), OPTIONAL, INTENT(INOUT) :: z
  QL algorithm with implicit shifts, to determine the eigenvalues and eigenvectors of a real,
  symmetric, tridiagonal matrix, or of a real, symmetric matrix previously reduced by tred2

```

§11.2. d is a vector of length N . On input, its elements are the diagonal elements of the tridiagonal matrix. On output, it returns the eigenvalues. The vector e inputs the subdiagonal elements of the tridiagonal matrix, with $e(1)$ arbitrary. On output e is destroyed. When finding only the eigenvalues, the optional argument z is omitted. If the eigenvectors of a tridiagonal matrix are desired, the $N \times N$ matrix z is input as the identity matrix. If the eigenvectors of a matrix that has been reduced by `tred2` are required, then z is input as the matrix output by `tred2`. In either case, the k th column of z returns the normalized eigenvector corresponding to $d(k)$.

Look for a single small subdiagonal element to split the matrix.

Form shift.

This is $d_m - k_s$.

A plane rotation as in the original QL , followed by Givens rotations to restore tridiagonal form.

Recover from underflow.

Form eigenvectors.

The routine `tqli` is intrinsically serial. A parallel replacement based on a divide and conquer algorithm has been proposed [1,2]. The idea is to split the tridiagonal matrix recursively into two tridiagonal matrices of

half the size plus a correction. Given the eigensystems of the two smaller tridiagonal matrices, it is possible to join them together and add in the effect of the correction. When some small size of tridiagonal matrix is reached during the recursive splitting, its eigensystem is found directly with a routine like `tqli`. Each of these small problems is independent and can be assigned to an independent processor. The procedures for sewing together can also be done independently. For very large matrices, this algorithm can be an order of magnitude faster than `tqli` even on a serial machine, and no worse than a factor of 2 or 3 slower, depending on the matrix. Unfortunately the parallelism is not well expressed in Fortran 90. Also, the sewing together requires quite involved coding. For an implementation see the LAPACK routine `SSTEDC`. Another parallel strategy for eigensystems uses inverse iteration, where each eigenvalue and eigenvector can be found independently [3].

This routine uses `z` as an optional argument that is required only if eigenvectors are being found as well as eigenvalues.

`iterate:` do See discussion of named do loops after `simplx` on p. 1219.

Carry out the elimination.

f90 *y*(*m*+1:*n*)=... If the four lines of code starting here were all coded for a serial machine in a single do-loop starting with *do i=m+1,n* (see Volume 1), it would pay to test whether *y* was zero because the next three lines could then be skipped for that value of *i*. There is no convenient way to do this here, even with a *where*, since the shape of the arrays on each of the three lines is different. For a parallel machine it is probably best just to do a few unnecessary multiplies and skip the test for zero values of *y*.

```

Go back for next iteration on current eigen-
value.

`anorm=sum(abs(a),mask=upper_triangle(n,n,extra=2))` See the discussion of `upper_triangle` after `jacobi` on p. 1226. Setting `extra=2` here picks out the upper Hessenberg part of the matrix.

`iterate: do` We use a named loop to improve the readability and structuring of the routine. The if-blocks that test for one or two roots end with `exit iterate`, transferring control back to the outermost loop and thus starting a search for the next root.

`call diagadd...` The routines that operate on the diagonal of a matrix are collected in `nrutil` partly so you can write clear code and partly in the hope that compiler writers will provide parallel library routines. Fortran 90 does not provide convenient parallel access to the diagonal of a matrix.

Chapter B12. Fast Fourier Transform

The algorithms underlying the parallel routines in this chapter are described in §22.4. As described there, the basic building block is a routine for simultaneously taking the FFT of each row of a two-dimensional matrix:

```

SUBROUTINE fourrow_sp(data,isign)
USE nrtype; USE nrutil, ONLY : assert,swap
IMPLICIT NONE
COMPLEX(SPC), DIMENSION(:,,:), INTENT(INOUT) :: data
INTEGER(I4B), INTENT(IN) :: isign
    Replaces each row (constant first index) of data(1:M,1:N) by its discrete Fourier trans-
    form (transform on second index), if isign is input as 1; or replaces each row of data
    by N times its inverse discrete Fourier transform, if isign is input as -1. N must be an
    integer power of 2. Parallelism is M-fold on the first index of data.
INTEGER(I4B) :: n,i,istep,j,m,mmax,n2
REAL(DP) :: theta
COMPLEX(SPC), DIMENSION(size(data,1)) :: temp
COMPLEX(DPC) :: w,wp                                     Double precision for the trigonometric recurrences.
COMPLEX(SPC) :: ws
n=size(data,2)
call assert(iand(n,n-1)==0, 'n must be a power of 2 in fourrow_sp')
n2=n/2
j=n2
    This is the bit-reversal section of the routine.
do i=1,n-2
    if (j > i) call swap(data(:,j+1),data(:,i+1))
    m=n2
    do
        if (m < 2 .or. j < m) exit
        j=j-m
        m=m/2
    end do
    j=j+m
end do
mmax=1
    Here begins the Danielson-Lanczos section of the routine.
do
    if (n <= mmax) exit
    istep=2*mmax
    theta=PI_D/(isign*mmax)
    wp=cplx(-2.0_dp*sin(0.5_dp*theta)**2,sin(theta),kind=dpc)
    w=cplx(1.0_dp,0.0_dp,kind=dpc)
    do m=1,mmax
        ws=w
        do i=m,n,istep
            j=i+mmax
            temp=ws*data(:,j)
            data(:,j)=data(:,i)-temp
            data(:,i)=data(:,i)+temp
        end do
        w=w*wp+w
    end do
    mmax=istep
    Outer loop executed log2 N times.
    Initialize for the trigonometric recurrence.
    Here are the two nested inner loops.
    This is the Danielson-Lanczos formula.
    Trigonometric recurrence.

```

```
end do
END SUBROUTINE fourrow_sp
```

f90 call assert(iand(n,n-1)==0 ... All the Fourier routines in this chapter require the dimension N of the data to be a power of 2. This is easily tested for by AND'ing N and $N - 1$: N should have the binary representation 10000..., in which case $N - 1 = 01111...$

```

This is the Danielson-Lanczos formula.

Trigonometric recurrence.

* * *

Here now are implementations of the method of §22.4 for the FFT of one-dimensional single- and double-precision complex arrays:

```
SUBROUTINE four1_sp(data,isign)
USE nrtype; USE nrutil, ONLY : arth,assert
USE nr, ONLY : fourrow
IMPLICIT NONE
COMPLEX(SPC), DIMENSION(:), INTENT(INOUT) :: data
INTEGER(I4B), INTENT(IN) :: isign
  Replaces a complex array data by its discrete Fourier transform, if isign is input as 1;
  or replaces data by its inverse discrete Fourier transform times the size of data, if isign
  is input as -1. The size of data must be an integer power of 2. Parallelism is achieved
  by internally reshaping the input array to two dimensions. (Use this version if fourrow is
  faster than fourcol on your machine.)
COMPLEX(SPC), DIMENSION(:,:), ALLOCATABLE :: dat,temp
COMPLEX(DPC), DIMENSION(:), ALLOCATABLE :: w,wp
REAL(DP), DIMENSION(:), ALLOCATABLE :: theta
INTEGER(I4B) :: n,m1,m2,j
n=size(data)
call assert(iand(n,n-1)==0, 'n must be a power of 2 in four1_sp')
  Find dimensions as close to square as possible, allocate space, and reshape the input array.
m1=2**ceiling(0.5_sp*log(real(n,sp))/0.693147_sp)
m2=n/m1
allocate(dat(m1,m2),theta(m1),w(m1),wp(m1),temp(m2,m1))
dat=reshape(data,shape(dat))
call fourrow(dat,isign)
```

Transform on second index.

```

theta=arth(0,isign,m1)*TWOPI_D/n      Set up recurrence.
wp=cmplx(-2.0_dp*sin(0.5_dp*theta)**2,sin(theta),kind=dpc)
w=cmplx(1.0_dp,0.0_dp,kind=dpc)
do j=2,m2                               Multiply by the extra phase factor.
    w=w*wp+w
    dat(:,j)=dat(:,j)*w
end do

The above routines use `fourrow` exclusively, on the assumption that it is faster than its sibling `fourcol`. When that is the case (as we typically find), it is likely that `four1_sp` is also faster than Volume 1's scalar `four1`. The reason, on scalar machines, is that `fourrow`'s parallelism is taking better advantage of cache memory locality.

If `fourrow` is *not* faster than `fourcol` on your machine, then you should instead try the following alternative FFT version that uses `fourcol` only.

```

SUBROUTINE four1_alt(data,isign)
USE nrtype; USE nrutil, ONLY : arth,assert
USE nr, ONLY : fourcol
IMPLICIT NONE
COMPLEX(SPC), DIMENSION(:), INTENT(INOUT) :: data
INTEGER(I4B), INTENT(IN) :: isign

```

Replaces a complex array `data` by its discrete Fourier transform, if `isign` is input as 1; or replaces `data` by its inverse discrete Fourier transform times the size of `data`, if `isign` is

input as -1 . The size of data must be an integer power of 2. Parallelism is achieved by internally reshaping the input array to two dimensions. (Use this version *only* if `fourcol` is faster than `fourrow` on your machine.)

```
COMPLEX(SPC), DIMENSION(:,:), ALLOCATABLE :: dat,temp
COMPLEX(DPC), DIMENSION(:,:), ALLOCATABLE :: w,wp
REAL(DP), DIMENSION(:,:), ALLOCATABLE :: theta
INTEGER(I4B) :: n,m1,m2,j
n=size(data)
call assert(iand(n,n-1)==0, 'n must be a power of 2 in four1_alt')
  Find dimensions as close to square as possible, allocate space, and reshape the input array.
m1=2**ceiling(0.5_sp*log(real(n,sp))/0.693147_sp)
m2=n/m1
allocate(dat(m1,m2),theta(m1),w(m1),wp(m1),temp(m2,m1))
dat=reshape(data,shape(dat))
temp=transpose(dat)                                Transpose and transform on (original) second in-
call fourcol(temp,isign)                             dex.
theta=arth(0,isign,m1)*TWOPI_D/n                    Set up recurrence.
wp=cmplx(-2.0_dp*sin(0.5_dp*theta)**2,sin(theta),kind=dpc)
w=cmplx(1.0_dp,0.0_dp,kind=dpc)
do j=2,m2                                           Multiply by the extra phase factor.
  w=w*wp+w
  temp(j,:)=temp(j,:)*w
end do
dat=transpose(temp)                                Transpose, and transform on (original) first in-
call fourcol(dat,isign)                             dex.
temp=transpose(dat)                                Transpose and then reshape the result back to

USE nr, ONLY : four1
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: data
INTEGER(I4B), INTENT(IN) :: isign
COMPLEX(SPC), DIMENSION(:), OPTIONAL, TARGET :: zdata
    When isign = 1, calculates the Fourier transform of a set of  $N$  real-valued data points,
    input in the array data. If the optional argument zdata is not present, the data are replaced
    by the positive frequency half of its complex Fourier transform. The real-valued first and
    last components of the complex transform are returned as elements data(1) and data(2),
    respectively. If the complex array zdata of length  $N/2$  is present, data is unchanged and
    the transform is returned in zdata.  $N$  must be a power of 2. If isign = -1, this routine
    calculates the inverse transform of a complex data array if it is the transform of real data.
    (Result in this case must be multiplied by  $2/N$ .) The data can be supplied either in data,
    with zdata absent, or in zdata.

allocate(dat2(size(data, 2), size(data, 3), size(data, 1)))
dat2=reshape(data, shape=shape(dat2), order=(/3, 1, 2/))  Transpose.
call fourrow_3d(dat2, isign)           Transform in (original) first dimension.
allocate(dat3(size(data, 3), size(data, 1), size(data, 2)))
dat3=reshape(dat2, shape=shape(dat3), order=(/3, 1, 2/))  Transpose.
deallocate(dat2)
call fourrow_3d(dat3, isign)           Transform in (original) second dimension.
data=reshape(dat3, shape=shape(data), order=(/3, 1, 2/))  Transpose back to output order.
deallocate(dat3)
END SUBROUTINE four3

```

The `reshape` intrinsic, used with an `order=` parameter, is the multidimensional generalization of the two-dimensional transpose operation. The line

```
dat2=reshape(data, shape=shape(dat2), order=(/3, 1, 2/))
```

is equivalent to the do-loop

```

do j=1, size(data, 1)
  dat2(:, :, j)=data(j, :, :)
end do

```

Incidentally, we have found some Fortran 90 compilers that (for scalar machines) are significantly *slower* executing the `reshape` than executing the equivalent do-loop. This, of course, shouldn't happen, since the `reshape` basically *is* an implicit do-loop. If you find such inefficient behavior on your compiler, you should report it as a bug to your compiler vendor! (Only thus will Fortran 90 compilers be brought to mature states of efficiency.)

```

SUBROUTINE four3_alt(data, isign)
USE nrtype
USE nr, ONLY : fourcol_3d
IMPLICIT NONE
COMPLEX(SPC), DIMENSION(:, :, :), INTENT(INOUT) :: data
INTEGER(I4B), INTENT(IN) :: isign

```

Replaces a 3-d complex array `data` by its discrete 2-d Fourier transform, if `isign` is input as 1; or replaces `data` by its inverse 3-d discrete Fourier transform times the product of its three sizes, if `isign` is input as `-1`. All three of `data`'s sizes must be integer powers of 2 (this is checked for in `fourcol_3d`). Parallelism is by use of `fourcol_3d`. (Use this version *only* if `fourcol_3d` is faster than `fourrow_3d` on your machine.)

```

COMPLEX(SPC), DIMENSION(:, :, :), ALLOCATABLE :: dat2, dat3
call fourcol_3d(data, isign)           Transform in first dimension.
allocate(dat2(size(data, 2), size(data, 3), size(data, 1)))
dat2=reshape(data, shape=shape(dat2), order=(/3, 1, 2/))  Transpose.
call fourcol_3d(dat2, isign)           Transform in (original) second dimension.
allocate(dat3(size(data, 3), size(data, 1), size(data, 2)))
dat3=reshape(dat2, shape=shape(dat3), order=(/3, 1, 2/))  Transpose.
deallocate(dat2)
call fourcol_3d(dat3, isign)           Transform in (original) third dimension.
data=reshape(dat3, shape=shape(data), order=(/3, 1, 2/))  Transpose back to output order.
deallocate(dat3)
END SUBROUTINE four3_alt

```

Note that `four3` uses `fourrow_3d`, the three-dimensional counterpart of `fourrow`, while `four3_alt` uses `fourcol_3d`, the three-dimensional counterpart of `fourcol`. You may want to time these programs to see which is faster on your machine.

* * *

In Volume 1, a single routine named `rlft3` was able to serve both as a three-dimensional real FFT, and as a two-dimensional real FFT. The trick is that the Fortran 77 version doesn't care whether the input array data is dimensioned as two- or three-dimensional. Fortran 90 is not so indifferent, and better programming practice is to have two separate versions of the algorithm:

```
SUBROUTINE rlft2(data,spec,speq,sign)
USE nrtype; USE nrutil, ONLY : assert,assert_eq
USE nr, ONLY : four2
REAL(SP), DIMENSION(:,,:), INTENT(INOUT) :: data
COMPLEX(SPC), DIMENSION(:,,:), INTENT(INOUT) :: spec
COMPLEX(SPC), DIMENSION(:), INTENT(INOUT) :: speq
INTEGER(I4B), INTENT(IN) :: sign

  Given a two-dimensional real array data(1:M,1:N), this routine returns (for isign=1)
  the complex fast Fourier transform as two complex arrays: On output, spec(1:M/2,1:N)
  contains the zero and positive frequency values of the first frequency component, while
  speq(1:N) contains the Nyquist critical frequency values of the first frequency component.
  The second frequency components are stored for zero, positive, and negative frequencies,
  in standard wrap-around order. For isign=-1, the inverse transform (times M x N/2 as
  a constant multiplicative factor) is performed, with output data deriving from input spec
  and speq. For inverse transforms on data not generated first by a forward transform, make
  sure the complex input data array satisfies property (12.5.2). The size of all arrays must
  always be integer powers of 2.

* * *

Referring back to the discussion of parallelism, §22.4, that led to `four1`'s implementation with \sqrt{N} parallelism, you might wonder whether Fortran 90 provides sufficiently powerful high-level constructs to enable an FFT routine with N -fold parallelism. The answer is, “*It does*, but you wouldn’t want to use them!” Access to arbitrary interprocessor communication in Fortran 90 is through the mechanism of the “vector subscript” (one-dimensional array of indices in arbitrary order). When a vector subscript is on the right-hand side of an assignment statement, the operation performed is effectively a “gather”; when it is on the left-hand side, the operation is effectively a “scatter.”

It is quite possible to write the classic FFT algorithm in terms of gather and scatter operations. In fact, we do so now. The problem is efficiency: The computations involved in constructing the vector subscripts for the scatter/gather operations, and the actual scatter/gather operations themselves, tend to swamp the underlying very lean FFT algorithm. The result is very slow, though theoretically perfectly parallelizable, code. Since small-scale parallel (SSP) machines can saturate their processors with \sqrt{N} parallelism, while massively multiprocessor (MMP) machines inevitably come with architecture-optimized FFT library calls, there is really no niche for these routines, except as pedagogical demonstrations. We give here a one-dimensional routine, and also an arbitrary-dimensional routine modeled on Volume 1’s `fourn`. Note the complete absence of do-loops of size N ; the loops that remain are over $\log N$ stages, or over the number of dimensions.

```

SUBROUTINE four1_gather(data,isign)
USE nrtype; USE nrutil, ONLY : arth,assert
IMPLICIT NONE
COMPLEX(SPC), DIMENSION(:), INTENT(INOUT) :: data
INTEGER(I4B), INTENT(IN) :: isign

```

Replaces a complex array `data` by its discrete Fourier transform, if `isign` is input as 1; or replaces `data` by `size(data)` times its inverse discrete Fourier transform, if `isign` is input as -1 . The size of `data` must be an integer power of 2. This routine demonstrates coding the FFT algorithm in high-level Fortran 90 constructs. Generally the result is *very*

much slower than library routines coded for specific architectures, and also *significantly slower* than the parallelization-by-rows method used in the routine `four1`.

FUNCTION convlv(data,respns,isign)
USE nrtype; USE nrutil, ONLY : assert,nrerror
USE nr, ONLY : realft
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: data
REAL(SP), DIMENSION(:), INTENT(IN) :: respns
INTEGER(I4B), INTENT(IN) :: isign
REAL(SP), DIMENSION(size(data)) :: convlv

  Convolves or deconvolves a real data set data (of length  $N$ , including any user-supplied
  zero padding) with a response function respns, stored in wrap-around order in a real array
  of length  $M \leq N$ . ( $M$  should be an odd integer,  $N$  a power of 2.) Wrap-around order
  means that the first half of the array respns contains the impulse response function at
  positive times, while the second half of the array contains the impulse response function at
  negative times, counting down from the highest element respns( $M$ ). On input isign is
  +1 for convolution, -1 for deconvolution. The answer is returned as the function convlv,
  an array of length  $N$ . data has INTENT(INOUT) for consistency with realft, but is
  actually unchanged.

END FUNCTION convlv

```

f90 `tmptr(1)=cmplx(...kind=spc)` The intrinsic function `cmplx` returns a quantity of type default complex unless the `kind` argument is present. It is therefore a good idea always to include this argument. The intrinsic functions `real` and `aimag`, on the other hand, when called with a complex argument, return the same kind as their argument. So it is a good idea *not* to put in a `kind` argument for these. (In fact, `aimag` doesn't allow one.) Don't confuse these situations, regarding complex variables, with the completely unrelated use of `real` to convert a real or integer variable to a real value of specified kind. In this latter case, `kind` should be specified.

  Computes the correlation of two real data sets data1 and data2 of length N (including
  any user-supplied zero padding). N must be an integer power of 2. The answer is
  returned as the function correl, an array of length N. The answer is stored in wrap-
  around order, i.e., correlations at increasingly negative lags are in correl(N) on down to
  correl(N/2 + 1), while correlations at increasingly positive lags are in correl(1) (zero
  lag) on up to correl(N/2). Sign convention of this routine: if data1 lags data2, i.e.,
  is shifted to the right of it, then correl will show a peak at positive lags.
COMPLEX(SPC), DIMENSION(size(data1)/2) :: cdat1,cdat2

f90 The Fortran 90 optional argument feature allows us to make unit 9 the default output unit in this routine, but leave the user the option of specifying a different output unit by supplying an actual argument for unit. We also use an optional argument to allow the user the option of overriding the default selection of the Bartlett window function.

FUNCTION window(j,facm,facp,nn_window) In Fortran 77 we coded this as a statement function. Here the internal function is equivalent, but allows full specification of the interface and so is preferred.

`jmax=imaxloc...` See discussion of `imaxloc` on p. 1017.

if (`x == real(ix,sp)`) then Without the explicit kind type parameter `sp`, `real` returns a value of type default real for an integer argument. This prevents automatic conversion of the routine from single to double precision. Here all you have to do is redefine `sp` in `nrtype` to get double precision.

★ ★ ★

```

SUBROUTINE dftcor(w,delta,a,b,endpts,corre,corim,corfac)
USE nrtype; USE nrutil, ONLY : assert
IMPLICIT NONE
REAL(SP), INTENT(IN) :: w,delta,a,b
REAL(SP), INTENT(OUT) :: corre,corim,corfac
REAL(SP), DIMENSION(:), INTENT(IN) :: endpts

```

For an integral approximated by a discrete Fourier transform, this routine computes the correction factor that multiplies the DFT and the endpoint correction to be added. Input is the angular frequency `w`, stepsize `delta`, lower and upper limits of the integral `a` and `b`, while the array `endpts` of length 8 contains the first 4 and last 4 function values. The

```

correction factor  $W(\theta)$  is returned as corfac, while the real and imaginary parts of the
endpoint correction are returned as corre and corim.

REAL(SP), INTENT(OUT) :: cosint,sinint
INTERFACE
  FUNCTION func(x)
    USE nrtype
    IMPLICIT NONE
    REAL(SP), DIMENSION(:), INTENT(IN) :: x
    REAL(SP), DIMENSION(size(x)) :: func
  END FUNCTION func
END INTERFACE

```

```

INTEGER(I4B), PARAMETER :: M=64,NDFT=1024,MPOL=6

```

Example subroutine illustrating how to use the routine `dftcor`. The user supplies an external function `func` that returns the quantity $h(t)$. The routine then returns $\int_a^b \cos(\omega t) h(t) dt$ as `cosint` and $\int_a^b \sin(\omega t) h(t) dt$ as `sinint`.

Parameters: The values of `M`, `NDFT`, and `MPOL` are merely illustrative and should be optimized for your particular application. `M` is the number of subintervals, `NDFT` is the length of the FFT (a power of 2), and `MPOL` is the degree of polynomial interpolation used to obtain the desired frequency from the FFT.

```

INTEGER(I4B) :: nn
INTEGER(I4B), SAVE :: init=0
INTEGER(I4B), DIMENSION(MPOL) :: nnmpol
REAL(SP) :: c,cdft,cerr,corfac,corim,corre,en,s,sdft,serr
REAL(SP), SAVE :: delta
REAL(SP), DIMENSION(MPOL) :: cpol,spol,xpol
REAL(SP), DIMENSION(NDFT), SAVE :: data
REAL(SP), DIMENSION(8), SAVE :: endpts
REAL(SP), SAVE :: aold=-1.0e30_sp,bold=-1.0e30_sp
if (init /= 1 .or. a /= aold .or. b /= bold) then
  init=1
  aold=a
  bold=b
  delta=(b-a)/M
  data(1:M+1)=func(a+arth(0,1,M+1)*delta)
  Load the function values into the data array.
  data(M+2:NDFT)=0.0
  Zero pad the rest of the data array.
  endpts(1:4)=data(1:4)
  Load the endpoints.
  endpts(5:8)=data(M-2:M+1)
  call realft(data(1:NDFT),1)
  realft returns the unused value corresponding to  $\omega_{N/2}$  in data(2). We actually want
  this element to contain the imaginary part corresponding to  $\omega_0$ , which is zero.
  data(2)=0.0
end if

```

Do we need to initialize, or is only ω changed?

Now interpolate on the DFT result for the desired frequency. If the frequency is an ω_n , i.e., the quantity `en` is an integer, then `cdft=data(2*en-1)`, `sdft=data(2*en)`, and you could omit the interpolation.

```

en=w*delta*NDFT/TWOPI+1.0_sp
nn=min(max(int(en-0.5_sp*MPOL+1.0_sp),1),NDFT/2-MPOL+1)
nnmpol=arth(nn,1,MPOL)
cpol(1:MPOL)=data(2*nnmpol(:)-1)
spol(1:MPOL)=data(2*nnmpol(:))
xpol(1:MPOL)=nnmpol(:)
call polint(xpol,cpol,en,cdft,cerr)
call polint(xpol,spol,en,sdft,serr)
call dftcor(w,delta,a,b,endpts,corre,corim,corfac)
cdft=cdft*corfac+corre
sdft=sdft*corfac+corim
c=delta*cos(w*a)
s=delta*sin(w*a)
cosint=c*cdft-s*sdft

```

Leftmost point for the interpolation.

Now get the endpoint correction and the multiplicative factor $W(\theta)$.

Finally multiply by Δ and $\exp(i\omega a)$.

```
sinint=s*cdft+c*sdf
END SUBROUTINE dftint
```

END SUBROUTINE pwtset

```

f90 Here we need to have as global variables arrays whose dimensions are known only at run time. At first sight the situation is the same as with the module `fminln` in `newt` on p. 1197. If you review the discussion there and in §21.5, you will recall that there are two good ways to implement this: with allocatable arrays (“Method 1”) or with pointers (“Method 2”). There is a difference here that makes allocatable arrays simpler. We do not wish to deallocate the arrays on exiting `pwtset`. On the contrary, the values in `cc` and `cr` need to be preserved for use in `pwt`. Since allocatable arrays are born in the well-defined state of “not currently allocated,” we can declare the arrays here as

```
REAL(SP), DIMENSION(:), ALLOCATABLE, SAVE :: cc,cr
```

and test whether they were used on a previous call with

```

if (allocated(cc)) deallocate(cc)
if (allocated(cr)) deallocate(cr)

```

We are then ready to allocate the new storage:

```
allocate(cc(n),cr(n))
```

With pointers, we would need the additional machinery of nullifying the pointers on the initial call, since pointers are born in an undefined state (see §21.5).

There is an additional important point in this example. The module variables need to be used by a “sibling” routine, `pwt`. We need to be sure that they do not become undefined when we exit `pwtset`. We could ensure this by putting a `USE pwtcom` in the main program that calls both `pwtset` and `pwt`, but it’s easy to forget to do this. It is preferable to put explicit `SAVE`s on all the module variables.

```

SUBROUTINE pwt(a, isign)
USE nrtype; USE nrutil, ONLY : arth, nrerror
USE pwtcom
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: a
INTEGER(I4B), INTENT(IN) :: isign

```

Partial wavelet transform: applies an arbitrary wavelet filter to data vector `a` (for `isign=1`) or applies its transpose (for `isign=-1`). Used hierarchically by routines `wt1` and `wtn`. The actual filter is determined by a preceding (and required) call to `pwtset`, which initializes the module `pwtcom`.

```

  n1=size(data1)
  n2=size(data2)
  en1=n1
  en2=n2
  dat(1:n1)=data1
  dat(n1+1:)=data2

```

Copy the two data sets into a single array.

```

org(1:n1)=0.0
org(n1+1:)=1.0
call sort2(dat,org)
Sort the array of 1's and 0's into the order of the merged data sets.
d=maxval(abs(cumsum(org)/en2-cumsum(1.0_sp-org)/en1))
Now use cumsum to get the c.d.f. corresponding to each set of data.
en=sqrt(en1*en2/(en1+en2))
prob=probks((en+0.12_sp+0.11_sp/en)*d)
Compute significance.
END SUBROUTINE kstwo

```

The problem here is how to compute the cumulative distribution function (c.d.f.) corresponding to each set of data, and then find the corresponding KS statistic, without a serial loop over the data. The trick is to define an array that contains 0 when the corresponding element comes from the first data set and 1 when it's from the second data set. Sort the array of 1's and 0's into the same order as the merged data sets. Now tabulate the partial sums of the array. Every time you encounter a 1, the partial sum increases by 1. So if you normalize the partial sums by dividing by the number of elements in the second data set, you have the c.d.f. of the second data set.

If you subtract the array of 1's and 0's from an array of all 1's, you get an array where 1 corresponds to an element in the first data set, 0 the second data set. So tabulating its partial sums and normalizing gives the c.d.f. of the first data set. As we've seen before, tabulating partial sums can be done with a parallel algorithm (cumsum in nrutil). The KS statistic is just the maximum absolute difference of the c.d.f.'s, computed in parallel with Fortran 90's maxval function.

```

Sort each of the data arrays, and convert the entries to ranks. The values sf and sg return the sums $\sum(f_k^3 - f_k)$ and $\sum(g_m^3 - g_m)$, respectively.

Sum the squared difference of ranks.

Expectation value of D , and variance of D give number of standard deviations, and significance.

Rank correlation coefficient, and its t value, give its significance.

Index vector.

Boundary; the first element must be zero. Assign ranks ignoring possible ties. No ties—we're done.

```

    Look for 0 → 1 transitions in tie, which mean that the 0 element is the start of a tie run.
    Store index of each transition in tstart. nties is the number of ties found.
    tend(1:nties)=pack(idx(:),tie(:)>eoshift(tie(:),1))
    Look for 1 → 0 transitions in tie, which mean that the 1 element is the end of a tie run.
    do i=1,nties                                Midrank assignments.
        w(tstart(i):tend(i))=(tstart(i)+tend(i))/2.0_sp
    end do
    tend(1:nties)=tend(1:nties)-tstart(1:nties)+1    Now calculate s.
    s=sum(tend(1:nties)**3-tend(1:nties))
    END SUBROUTINE crank
    END SUBROUTINE spear

```

To understand how the parallel version of `crank` works, let's consider an example of 9 elements in the array `w`, which is input in sorted order to `crank`. The elements in our example are given in the second line of the following table:

index	1	2	3	4	5	6	7	8	9
data in <code>w</code>	0	0	1	1	1	2	3	4	4
shift right	0	0	0	1	1	1	2	3	4
compare	1	1	0	1	1	0	0	0	1
tie array	0	1	0	1	1	0	0	0	1
shift left	1	0	1	1	0	0	0	1	0
0 → 1	1		3					8	
1 → 0		2			5			9	
									start index
									stop index

We look for ties by comparing this array with itself, right shifted by one element (“shift right” in table). We record a 1 for each element that is the same, a 0 for each element that is different (“compare”). A 1 indicates the element is part of a tie with the *preceding* element, so we always set the first element to 0, even if it was a 1 as in our example. This gives the “tie array.” Now wherever the tie array makes a transition 0 → 1 indicates the start of a tie run, while a 1 → 0 transition indicates the end of a tie run. We find these transitions by comparing the tie array to itself left shifted by one (“shift left”). If the tie array element is smaller than the shifted array element, we have a 0 → 1 transition and we record the corresponding index as the start of a tie. Similarly if the tie array element is larger we record the index as the end of a tie. Note that the shifts must be end-off shifts with zeros inserted in the gaps for the boundary conditions to work.

```

call array_copy(pack(idx(:),tie(:)<eoshift(tie(:),1)),
               tstart,nties,ndum)

```

The start indices (1, 3, and 8 in our example above) are here packed into the first few elements of `tstart`. `array_copy` is a useful routine in `nrutil` for copying elements from one array to another, when the number of elements to be copied is not known in advance. This line of code is equivalent to

```

tstart(:)=0
tstart(:)=pack(idx(:), tie(:) < eoshift(tie(:),1),tstart(:))
nties=count(tstart(:) > 0)

```

The point is that we don't know how many elements `pack` is going to select. We have to make sure the dimensions of both sides of the `pack` statement are the same,

so we set the optional third argument of `pack` to `tstart`. We then make a separate pass through `tstart` to count how many elements we copied. Alternatively, we could have used an additional logical array `mask` and coded this as

```
mask(:)=tie(:) < eoshift(tie(:),1)
nties=count(mask)
tstart(1:nties)=pack(idx(:),mask)
```

But we still need two passes through the `mask` array. The beauty of the `array_copy` routine is that `nties` is determined from the *size* of the first argument, without the necessity for a second pass through the array.

prob=erfcc(abs(z)/SQRT2)
END SUBROUTINE kend12
```

Get cumulative sums leftward along rows.

Tally the extra-y pairs.
Get counts of points to lower-right of each cell in cum.

Total number of entries in table.
Tally the concordant pairs.
Now get counts of points to upper-right of each cell in cum,

giving tally of discordant points.
Finally, get cumulative sums upward along columns,

giving the count of extra-x pairs, and compute desired results.

The underlying algorithm in kend12 might seem to require looping over all *pairs* of cells in the two-dimensional table *tab*. Actually, however, clever use of the *cumsum* utility function reduces this to a simple loop over all the cells; moreover this “loop” parallelizes into a simple parallel product and call to the *sum* intrinsic. The basic idea is shown in the following table:

		<i>d</i>	<i>d</i>
	<i>t</i>	<i>y</i>	<i>y</i>
	<i>x</i>	<i>c</i>	<i>c</i>
	<i>x</i>	<i>c</i>	<i>c</i>
	<i>x</i>	<i>c</i>	<i>c</i>

Relative to the cell marked *t* (which we use to denote the numerical value it contains), the cells marked *d* contribute to the “discordant” tally in Volume 1’s equation (14.6.8),

while the cells marked c contribute to the “concordant” tally. Likewise, the cells marked x and y contribute, respectively, to the “extra- x ” and “extra- y ” tallies. What about the cells left blank? Since we want to count pairs of cells only *once*, without duplication, these cells will be counted, relative to the location shown as t , when t itself moves into the blank-cell area.

Symbolically we have

$$\begin{aligned}
 \text{concordant} &= \sum_n t_n \left(\sum_{\text{lower right}} c_m \right) \\
 \text{discordant} &= \sum_n t_n \left(\sum_{\text{upper right}} d_m \right) \\
 \text{extra-}x &= \sum_n t_n \left(\sum_{\text{below}} x_m \right) \\
 \text{extra-}y &= \sum_n t_n \left(\sum_{\text{to the right}} y_m \right)
 \end{aligned} \tag{B14.1}$$

Here n varies over all the positions in the table, while the limits of the inner sums are relative to the position of n . (The letters t_n , c_m , d_m , x_m , y_m all represent the value in a cell; we use different letters only to make the relation with the above table clear.) Now the final trick is to recognize that the inner sums, over cells to the lower- or upper-right, below, and to the right can be done in parallel by cumulative sums (cumsum) sweeping to the right and up. The routine does these in a nonintuitive order merely to be able to reuse maximally the scratch spaces cum and cumt.

END SUBROUTINE fit

```

For unweighted data evaluate typical sig using chi2, and adjust the standard deviations.

f90 REAL(SP), DIMENSION(:), POINTER :: wt...wt=>t When standard deviations are supplied in sig, we need to compute the weights for the least squares fit in a temporary array wt. Later in the routine, we need another temporary array, which we call t to correspond to the variable in equation (15.2.15). It would be confusing to use the same name for both arrays. In Fortran 77 the arrays could share storage with an EQUIVALENCE declaration, but that is a deprecated feature in Fortran 90. We accomplish the same thing by making wt a pointer alias to t.

REAL(SP), PARAMETER :: POTN=1.571000_sp,BIG=1.0e30_sp,ACC=1.0e-3_sp

```

Straight-line fit to input data x and y with errors in both x and y , the respective standard deviations being the input quantities sigx and sigy . x , y , sigx , and sigy are all arrays of the same length. Output quantities are a and b such that $y = a + bx$ minimizes χ^2 , whose value is returned as chi2 . The χ^2 probability is returned as q , a small value indicating a poor fit (sometimes indicating underestimated errors). Standard errors on a and b are returned as siga and sigb . These are not meaningful if either (i) the fit is poor, or (ii) b is so large that the data are consistent with a vertical (infinite b) line. If siga and sigb are returned as BIG , then the data are consistent with *all* values of b .

Given a set of N data points x , y with individual standard deviations sig , all arrays of length N , use χ^2 minimization to fit for some or all of the M coefficients a of a function that depends linearly on a , $y = \sum_{i=1}^M a_i \times afunc_i(x)$. The input logical array $maska$ of length M indicates by true entries those components of a that should be fitted for, and by false entries those components that should be held fixed at their input values. The program returns values for a , $\chi^2 = chisq$, and the $M \times M$ covariance matrix $covar$. (Parameters held fixed will return zero variances.) The user supplies a subroutine $funcs(x, afunc)$ that returns the M basis functions evaluated at $x = x$ in the array $afunc$.

```

Given a set of N data points x, y with individual standard deviations sig , all arrays of length N , use χ^2 minimization to determine the M coefficients a of a function that depends linearly on a , $y = \sum_{i=1}^M a_i \times \text{afunc}_i(x)$. Here we solve the fitting equations using singular value decomposition of the $N \times M$ matrix, as in §2.6. On output, the $M \times M$ array v and the vector w of length M define part of the singular value decomposition, and can be used to obtain the covariance matrix. The program returns values for the M fit parameters a , and χ^2 , chisq . The user supplies a function $\text{funcs}(x, \text{afunc})$ that returns the M basis functions evaluated at $x = X$ in the array afunc .

Parameter: Above value of TOL is for single precision and variables scaled to order unity.

```

INTEGER(I4B) :: i,ma,n

where (w < TOL*maxval(w)) w=0.0
call svbksb(u,w,v,b,a)
chisq=vabs(matmul(usav,a)-b)**2
END SUBROUTINE svdfit

```

Accumulate coefficients of the fitting matrix in u .

Singular value decomposition.

Edit the singular values, given TOL from the parameter statement.

Evaluate chi-square.

f90 $u = \text{usav} * \text{spread}(\text{sigi}, \text{dim}=2, \text{ncopies}=\text{ma})$ Remember how `spread` works: the vector sigi is copied *along* the dimension 2, making a matrix whose columns are each a copy of sigi . The multiplication here is element by element, so each row of usav is multiplied by the corresponding element of sigi .

$\text{chisq} = \text{vabs}(\text{matmul}(\text{usav}, a) - b) ** 2$ Fortran 90's `matmul` intrinsic allows us to evaluate χ^2 from the mathematical definition in terms of matrices. `vabs` in `nrutil` returns the length of a vector (L_2 norm).

```

SUBROUTINE svdvar(v,w,cvm)
USE nrtype; USE nrutil, ONLY : assert_eq
IMPLICIT NONE
REAL(SP), DIMENSION(:,:), INTENT(IN) :: v
REAL(SP), DIMENSION(:), INTENT(IN) :: w
REAL(SP), DIMENSION(:,:), INTENT(OUT) :: cvm

```

To evaluate the covariance matrix *cvm* of the fit for *M* parameters obtained by *svdfit*, call this routine with matrices *v*, *w* as returned from *svdfit*. The dimensions are *M* for *w* and *M* × *M* for *v* and *cvm*.

```

INTEGER(I4B) :: ma
REAL(SP), DIMENSION(size(w)) :: wti

END INTERFACE

```

Levenberg-Marquardt method, attempting to reduce the value χ^2 of a fit between a set of N data points x , y with individual standard deviations sig , and a nonlinear function dependent on M coefficients a . The input logical array maska of length M indicates by true entries those components of a that should be fitted for, and by false entries those components that should be held fixed at their input values. The program returns current best-fit values for the parameters a , and $\chi^2 = \text{chisq}$. The $M \times M$ arrays covar and α are used as working space during most iterations. Supply a subroutine $\text{funcs}(x,a,y\text{fit},dyda)$ that evaluates the fitting function $y\text{fit}$, and its derivatives $dyda$ with respect to the fitting parameters a at x . On the first call provide an initial guess for the parameters a , and set $\text{alamda} < 0$ for initialization (which then sets $\text{alamda} = .001$). If a step succeeds chisq becomes smaller and alamda decreases by a factor of 10. If a step fails alamda grows by a factor of 10. You must call this routine repeatedly until convergence is achieved. Then, make one final call with $\text{alamda} = 0$, so that covar returns the covariance matrix, and α the curvature matrix. (Parameters held fixed will return zero covariances.)

END SUBROUTINE mrqcof
END SUBROUTINE mrqmin

```

The organization of this routine is similar to that of *amoeba*, discussed on p. 1209. We want to keep the argument list of *mrqcof* to a minimum, but we want to make clear what global variables it accesses, and protect *mrqmin_private*'s name space.

REAL(SP), DIMENSION(:), ALLOCATABLE, SAVE :: atry,beta These arrays, as well as *da*, are allocated with the correct dimensions on the first call to *mrqmin*.

They need to retain their values between calls, so they are declared with the SAVE attribute. They get deallocated only on the final call when `alamda=0`.

`call diagmult(...)` See discussion of `diagadd` after `hqr` on p. 1234.

`atry=a+unpack(da(1:mfit,1),maska,0.0_sp)` `maska` controls which elements of `a` get incremented by `da` and which by 0.

Least squares solutions.

The standard deviation will give some idea of how big an iteration step to take.

Guess bracket as $3\text{-}\sigma$ away, in the downhill direction known from f_1 .

Bracketing.

Refine until error a negligible number of standard deviations.

Bisection.

```
END FUNCTION rofunc  
END SUBROUTINE medfit
```

f90 The organization of this routine is similar to that of *amoeba* discussed on p. 1209. We want to keep the argument list of *rofunc* to a minimum, but we want to make clear what global variables it accesses and protect *medfit_private*'s name space. In the Fortran 77 version, we kept the only argument as *b* by passing the global variables in a common block. This required us to make copies of the arrays *x* and *y*. An alternative Fortran 90 implementation would be to use a module with pointers to the arguments of *medfit* like *x* and *y* that need to be passed to *rofunc*. We think the *medfit_private* construction is simpler.

Also input are the stepsize to be attempted $htry$, the required accuracy eps , and the vector $yscal$ against which the error is scaled. On output, y and x are replaced by their new values, $hdid$ is the stepsize that was actually accomplished, and $hnext$ is the estimated next stepsize. `derivs` is the user-supplied subroutine that computes the right-hand-side derivatives. y , $dydx$, and $yscal$ must all have the same length. Be sure to set $htry$ on successive steps to the value of $hnext$ returned from the previous step, as is the case if the routine is called by `odeint`.

Parameters: $KMAXX$ is the maximum row number used in the extrapolation; $IMAX$ is the next row number; $SAFE1$ and $SAFE2$ are safety factors; $REDMAX$ is the maximum factor used when a stepsize is reduced, $REDMIN$ the minimum; $TINY$ prevents division by zero; $1/SCALMX$ is the maximum factor by which a stepsize can be increased.

    end if
  end if
END SUBROUTINE bsstep

```

f90

`a(:)=cumsum(nseq,1)` The function `cumsum` in `nrutil` with the optional argument `seed=1` gives a direct implementation of equation (16.4.6).

`where (upper_triangle(KMAXX,KMAXX))...` The `upper_triangle` function in `nrutil` returns an upper triangular logical mask. As used here, the mask is true everywhere in the upper triangle of a $KMAXX \times KMAXX$ matrix, excluding the diagonal. An optional integer argument `extra` allows additional diagonals to be set to true. With `extra=1` the upper triangle including the diagonal would be true.

`main_loop: do` Using a named do-loop provides clear structured code that required goto's in the Fortran 77 version.

`kopt=1+iminloc(...)` See the discussion of `imaxloc` on p. 1017.

Fourth order Rosenbrock step for integrating stiff ODEs, with monitoring of local trunca-
tion error to adjust stepsize. Input are the dependent variable vector y and its derivative
dydx at the starting value of the independent variable x. Also input are the stepsize
to be attempted htry, the required accuracy eps, and the vector yscal against which the
error is scaled. On output, y and x are replaced by their new values, hdid is the stepsize
that was actually accomplished, and hnext is the estimated next stepsize. derivs is a
user-supplied subroutine that computes the derivatives of the right-hand side with respect
to x, while jacobn (a fixed name) is a user-supplied subroutine that computes the Jacobi
matrix of derivatives of the right-hand side with respect to the components of y. y, dydx,
and yscal must have the same length.
Parameters: GROW and SHRNK are the largest and smallest factors by which stepsize can
change in one step; ERRCON=(GROW/SAFETY)**(1/PGROW) and handles the case when
errmax  $\simeq$  0.

```

Semi-implicit extrapolation step for integrating stiff ODEs, with monitoring of local truncation error to adjust stepsize. Input are the dependent variable vector *y* and its derivative *dydx* at the starting value of the independent variable *x*. Also input are the stepsize to be attempted *htry*, the required accuracy *eps*, and the vector *yscal* against which the error is scaled. On output, *y* and *x* are replaced by their new values, *hdid* is the stepsize that was actually accomplished, and *hnext* is the estimated next stepsize. *derivs* is a user-supplied subroutine that computes the derivatives of the right-hand side with respect to *x*, while *jacobn* (a fixed name) is a user-supplied subroutine that computes the Jacobi matrix of derivatives of the right-hand side with respect to the components of *y*. *y*, *dydx*, and *yscal* must all have the same length. Be sure to set *htry* on successive steps to the value of *hnext* returned from the previous step, as is the case if the routine is called by *odeint*.

Chapter B17. Two Point Boundary Value Problems

```
! FUNCTION shoot(v) is named "funcv" for use with "newt"
FUNCTION funcv(v)
  USE nrtype
  USE nr, ONLY : odeint, rkqs
  USE sphoot_caller, ONLY : nvar, x1, x2; USE ode_path, ONLY : xp, yp
  IMPLICIT NONE
  REAL(SP), DIMENSION(:), INTENT(IN) :: v
  REAL(SP), DIMENSION(size(v)) :: funcv
  REAL(SP), PARAMETER :: EPS=1.0e-6_sp
```

Routine for use with `newt` to solve a two point boundary value problem for N coupled ODEs by shooting from x_1 to x_2 . Initial values for the ODEs at x_1 are generated from the n_2 input coefficients v , using the user-supplied routine `load`. The routine integrates the ODEs to x_2 using the Runge-Kutta method with tolerance `EPS`, initial stepsize `h1`, and minimum stepsize `hmin`. At x_2 it calls the user-supplied subroutine `score` to evaluate the n_2 functions `funcv` that ought to be zero to satisfy the boundary conditions at x_2 . The functions `funcv` are returned on output. `newt` uses a globally convergent Newton's method to adjust the values of v until the functions `funcv` are zero. The user-supplied subroutine `derivs(x,y,dydx)` supplies derivative information to the ODE integrator (see Chapter 16). The module `sphoot_caller` receives its values from the main program so that `funcv` can have the syntax required by `newt`. Set `nvar = N` in the main program.

FUNCTION funcv(v)
  USE nrtype
  USE nr, ONLY : odeint,rkqs
  USE sphfpt_caller, ONLY : x1,x2,xf,nn2; USE ode_path, ONLY : xp,yp
  IMPLICIT NONE
  REAL(SP), DIMENSION(:), INTENT(IN) :: v
  REAL(SP), DIMENSION(size(v)) :: funcv
  REAL(SP), PARAMETER :: EPS=1.0e-6_sp
  Routine for use with newt to solve a two point boundary value problem for  $N$  coupled
  ODEs by shooting from  $x_1$  and  $x_2$  to a fitting point  $x_f$ . Initial values for the ODEs at
   $x_1$  ( $x_2$ ) are generated from the  $n_2$  ( $n_1$ ) coefficients  $V_1$  ( $V_2$ ), using the user-supplied
  routine load1 (load2). The coefficients  $V_1$  and  $V_2$  should be stored in a single ar-
  ray  $v$  of length  $N$  in the main program, and referenced by pointers as  $v1=>v(1:n_2)$ ,
   $v2=>v(n_2+1:N)$ . Here  $N = n_1 + n_2$ . The routine integrates the ODEs to  $x_f$  using
  the Runge-Kutta method with tolerance  $EPS$ , initial stepsize  $h_1$ , and minimum stepsize
   $hmin$ . At  $x_f$  it calls the user-supplied subroutine score to evaluate the  $N$  functions  $f_1$ 
  and  $f_2$  that ought to match at  $x_f$ . The differences  $funcv$  are returned on output.  $newt$ 
  uses a globally convergent Newton's method to adjust the values of  $v$  until the functions
   $funcv$  are zero. The user-supplied subroutine  $derivs(x,y,dydx)$  supplies derivative in-
  formation to the ODE integrator (see Chapter 16). The module  $sphfpt\_caller$  receives
  its values from the main program so that  $funcv$  can have the syntax required by  $newt$ .
  Set  $nn2 = n_2$  in the main program.

INTEGER(I4B), DIMENSION(:), INTENT(IN) :: indexv
REAL(SP), DIMENSION(:,,:), INTENT(INOUT) :: y
  Driver routine for solution of two point boundary value problems with  $N$  equations by
  relaxation. itmax is the maximum number of iterations. conv is the convergence criterion
  (see text). slowc controls the fraction of corrections actually used after each iteration.
  scalv, a vector of length  $N$ , contains typical sizes for each dependent variable, used to
  weight errors. indexv, also of length  $N$ , lists the column ordering of variables used to
  construct the matrix s of derivatives. (The nb boundary conditions at the first mesh point
  must contain some dependence on the first nb variables listed in indexv.) There are a total
  of  $M$  mesh points. y is the  $N \times M$  array that contains the initial guess for all the dependent
  variables at each mesh point. On each iteration, it is updated by the calculated correction.

Chapter B18. Integral Equations and Inverse Theory

```
SUBROUTINE fred2(a,b,t,f,w,g,ak)
USE nrtype; USE nrutil, ONLY : assert_eq,unit_matrix
USE nr, ONLY : gauleg,lubksb,ludcmp
IMPLICIT NONE
REAL(SP), INTENT(IN) :: a,b
REAL(SP), DIMENSION(:), INTENT(OUT) :: t,f,w
INTERFACE
```

```
  FUNCTION g(t)
    USE nrtype
    IMPLICIT NONE
    REAL(SP), DIMENSION(:), INTENT(IN) :: t
    REAL(SP), DIMENSION(size(t)) :: g
    END FUNCTION g

  FUNCTION ak(t,s)
    USE nrtype
    IMPLICIT NONE
    REAL(SP), DIMENSION(:), INTENT(IN) :: t,s
    REAL(SP), DIMENSION(size(t),size(s)) :: ak
    END FUNCTION ak
END INTERFACE
```

Solves a linear Fredholm equation of the second kind by N -point Gaussian quadrature. On input, a and b are the limits of integration. g and ak are user-supplied external functions. g returns $g(t)$ as a vector of length N for a vector of N arguments, while ak returns $\lambda K(t, s)$ as an $N \times N$ matrix. The routine returns arrays t and f of length N containing the abscissas t_i of the Gaussian quadrature and the solution f at these abscissas. Also returned is the array w of length N of Gaussian weights for use with the Nystrom interpolation routine `fredin`.

```
INTEGER(I4B) :: n
INTEGER(I4B), DIMENSION(size(f)) :: indx
REAL(SP) :: d
REAL(SP), DIMENSION(size(f),size(f)) :: omk
n=assert_eq(size(f),size(t),size(w),'fred2')
call gauleg(a,b,t,w)
call unit_matrix(omk)
omk=omk-ak(t,t)*spread(w,dim=1,ncopies=n)
f=g(t)
call ludcmp(omk,indx,d)
call lubksb(omk,indx,f)
END SUBROUTINE fred2
```

Replace `gauleg` with another routine if not using Gauss-Legendre quadrature.
Form $1 - \lambda K$.

Solve linear equations.

`call unit_matrix(omk)` The `unit_matrix` routine in `nrutil` does exactly what its name suggests.

$\text{omk}=\text{omk}-\text{ak}(\text{t},\text{t})*\text{spread}(\text{w},\text{dim}=1,\text{ncopies}=\text{n})$ By now this idiom should be second nature: the first column of ak gets multiplied by the first element of w , and so on.

★ ★ ★

```

FUNCTION fredin(x,a,b,t,f,w,g,ak)
USE nrtype; USE nrutil, ONLY : assert_eq
IMPLICIT NONE
REAL(SP), INTENT(IN) :: a,b
REAL(SP), DIMENSION(:), INTENT(IN) :: x,t,f,w
REAL(SP), DIMENSION(size(x)) :: fredin

    IMPLICIT NONE
    REAL(SP), DIMENSION(:), INTENT(IN) :: t,s
    REAL(SP), DIMENSION(size(t),size(s)) :: ak
  END FUNCTION ak
END INTERFACE

Input are arrays  $\text{t}$  and  $\text{w}$  of length  $N$  containing the abscissas and weights of the  $N$ -point Gaussian quadrature, and the solution array  $\text{f}$  of length  $N$  from fred2. The function fredin returns the array of values of  $f$  at an array of points  $\text{x}$  using the Nystrom interpolation formula. On input,  $\text{a}$  and  $\text{b}$  are the limits of integration.  $\text{g}$  and  $\text{ak}$  are user-supplied external functions.  $\text{g}$  returns  $g(t)$  as a vector of length  $N$  for a vector of  $N$  arguments, while  $\text{ak}$  returns  $\lambda K(t,s)$  as an  $N \times N$  matrix.

INTEGER(I4B) :: n
n=assert_eq(size(f),size(t),size(w),'fredin')
fredin=g(x)+matmul(ak(x,t),w*f)
END FUNCTION fredin

```

f90

`fredin=g(x)+matmul...` Fortran 90 allows very concise coding here, which also happens to be much closer to the mathematical formulation than the loops required in Fortran 77.

    call lubksb(a,indx,b)
    f(:,i)=b(:)
end do
END SUBROUTINE voltra

```

Initialize.

Take a step h .

Accumulate right-hand side of linear equations in b .

Left-hand side goes in matrix a .

Solve linear equations.

f90 FUNCTION $g(t)$...REAL(SP), DIMENSION(:), POINTER :: g The routine *voltra* requires an argument that is a function returning a vector, but we don't know the dimension of the vector at compile time. The solution is to make the function return a *pointer* to the vector. This is not the same thing as a pointer to a function, which is not allowed in Fortran 90. When you use the pointer in the routine, Fortran 90 figures out from the context that you want the vector of values, so the code remains highly readable. Similarly, the argument ak is a function returning a pointer to a matrix.

The coding of the user-supplied functions g and ak deserves some comment: functions returning pointers to arrays are potential memory leaks if the arrays are allocated dynamically in the functions. Here the user knows in advance the dimension of the problem, and so there is no need to use dynamical allocation in the functions. For example, in a two-dimensional problem, you can code g as follows:

```

FUNCTION g(t)
USE nrtype
IMPLICIT NONE
REAL(SP), INTENT(IN) :: t
REAL(SP), DIMENSION(:), POINTER :: g
REAL(SP), DIMENSION(2), TARGET, SAVE :: gg
g=>gg
g(1)=...
g(2)=...
END FUNCTION g

```

and similarly for `ak`.

Suppose, however, we coded `g` with dynamical allocation:

```

FUNCTION g(t)
  USE nrtype
  IMPLICIT NONE
  REAL(SP), INTENT(IN) :: t
  REAL(SP), DIMENSION(:), POINTER :: g
  allocate(g(2))
  g(1)=...
  g(2)=...
END FUNCTION g

```

Now `g` never gets deallocated; each time we call the function fresh memory gets consumed. If you have a problem that really does require dynamical allocation in a pointer function, you have to be sure to deallocate the pointer in the calling routine. In `voltra`, for example, we would declare pointers `gtemp` and `aktemp`. Then instead of writing simply

```
b=g(t(i))+...
```

we would write

```

gtemp=>g(t(i))
b=gtemp+...
deallocate(gtemp)

```

and similarly for each pointer function invocation.

`call array_copy(g(t(1)),f(:,1),ncop,nerr)` The routine would work if we replaced this statement with simply `f(:,1)=g(t(1))`. The purpose of using `array_copy` from `nrutil` is that we can check that `f` and `g` have consistent dimensions with a call to `assert_eq`.

      d(3:jm2:2,2:jm1:2)*u(3:jm2:2,1:jm2:2)+&
      e(3:jm2:2,2:jm1:2)*u(3:jm2:2,2:jm1:2)-f(3:jm2:2,2:jm1:2)
    u(3:jm2:2,2:jm1:2)=u(3:jm2:2,2:jm1:2)-omega*&
      resid(3:jm2:2,2:jm1:2)/e(3:jm2:2,2:jm1:2)
    resid(2:jm1:2,3:jm2:2)=a(2:jm1:2,3:jm2:2)*u(3:jmax:2,3:jm2:2)+&
      b(2:jm1:2,3:jm2:2)*u(1:jm2:2,3:jm2:2)+&
      c(2:jm1:2,3:jm2:2)*u(2:jm1:2,4:jm1:2)+&
      d(2:jm1:2,3:jm2:2)*u(2:jm1:2,2:jm3:2)+&
      e(2:jm1:2,3:jm2:2)*u(2:jm1:2,3:jm2:2)-f(2:jm1:2,3:jm2:2)
    u(2:jm1:2,3:jm2:2)=u(2:jm1:2,3:jm2:2)-omega*&
      resid(2:jm1:2,3:jm2:2)/e(2:jm1:2,3:jm2:2)
    omega=1.0_dp/(1.0_dp-0.25_dp*rjac**2*omega)
    anorm=sum(abs(resid(2:jm1:2,jm1)))
    if (anorm < EPS*anormf) exit
  end do
  if (n > MAXITS) call nrerror('MAXITS exceeded in sor')
END SUBROUTINE sor

```

Red-black iterative schemes like the one used in `sor` are easily parallelizable. Updating the red grid points requires information only from the black grid points, so they can all be updated independently. Similarly the black grid points can all be updated independently. Since nearest neighbors are involved in the updating, communication costs can be kept to a minimum.

There are several possibilities for coding the red-black iteration in a data parallel way using only Fortran 90 and no parallel language extensions. One way is to define an $N \times N$ logical mask `red` that is true on the red grid points and false on the black. Then each iteration consists of an update governed by a `where(red)...``end where` block and a `where(.not. red)...``end where` block. We have chosen a more direct coding that avoids the need for storage of the array `red`. The red update corresponds to the even-even and odd-odd grid points, the black to the even-odd and odd-even points. We can code each of these four cases directly with array sections, as in the routine above.

The array section notation used in `sor` is rather dense and hard to read. We could use pointer aliases to try to simplify things, but since each array section is different, we end up merely giving names to each term that was there all along. Pointer aliases do help if we code `sor` using a logical mask. Since there may be machines on which this version is faster, and since it is of some pedagogic interest, we give the alternative code:

```

```

f90 The Fortran 90 version of `mglin` (and of `mgfas` below) is quite different from the Fortran 77 version, although the algorithm is identical. First, we use a recursive implementation. This makes the code much more transparent. It also makes the memory management much better: we simply define the new arrays `res` and `v` as automatic arrays of the appropriate dimension on each recursive call to a coarser level. And a third benefit is that it is trivial to change the code to increase the number of multigrid iterations done at level $j - 1$ by each iteration at level j , i.e., to set the quantity γ in §19.6 to a value greater than one. (Recall that $\gamma = 1$ as chosen in `mglin` gives V-cycles, $\gamma = 2$ gives W-cycles.) Simply enclose the recursive call in a do-loop:

```

      do i=1,merge(gamma,1,j /= 2)
        call mg(j-1,v,res)
      end do

```

The merge expression ensures that there is no more than one call to the coarsest level, where the problem is solved exactly.

A second improvement in the Fortran 90 version is to make the procedures `resid`, `interp`, and `rstrct` functions instead of subroutines. This allows us to code the algorithm exactly as written mathematically.

`TYPE ptr2d...` The right-hand-side quantity ρ is supplied initially on the finest grid in the argument `u`. It has to be defined on the coarser grids by restriction, and then supplied as the right-hand side to `mg` in the nested iteration loop. This loop starts at the coarsest level and progresses up to the finest level. We thus need a data structure to store ρ on all the grid levels. A convenient way to implement this in Fortran 90 is to define a type `ptr2d`, a pointer to a two-dimensional array `a` that represents a grid. (In three dimensions, a would of course be three-dimensional.) We then declare the variable ρ as an allocatable array of type `ptr2d`:

```

TYPE(ptr2d), ALLOCATABLE :: rho(:)

```

Next we allocate storage for ρ on each level. The number of levels or grids, `ng`, is known only at run time:

```

allocate(rho(ng))

```

Then we allocate storage as needed on particular sized grids. For example,

```

allocate(rho(ngrid)%a(nn,nn))

```

allocates an $nn \times nn$ grid for ρ on grid number `ngrid`.

The various subsidiary routines of `mglin` such as `rstrct` and `interp` are written to accept two-dimensional arrays as arguments. With the data structure we've employed, using these routines is simple. For example,

```

rho(ngrid)%a=rstrct(rho(ngrid+1)%a)

```

will restrict ρ from the grid `ngrid+1` to the grid `ngrid`. The statement is even more readable if we mentally ignore the `%a` that is tagged onto each variable. (If

we actually did omit %a in the code, the compiler would think we meant the array of type ptr2d instead of the grid array.)

Note that while Fortran 90 does not allow you to declare an array of pointers directly, you can achieve the same effect by declaring your own type, as we have done with ptr2d in this example.

See the discussion after `mglin` on p. 1336 for the changes made in the Fortran 90 versions of the multigrid routines from the Fortran 77 versions.

TYPE ptr2d... See discussion after `mglin` on p. 1336.

RECURSIVE SUBROUTINE `mg(j,u,rhs,trerr)` Recall that `mgfas` solves the problem $\mathcal{L}u = 0$, but that nonzero right-hand sides appear during the solution. We implement this by having rhs be an optional argument to `mg`. On the first call at a given level j , the right-hand side is zero and so you just omit it from the calling sequence. On the other hand, the truncation error `trerr` is computed only on the first call at a given level, so it is also an optional argument that does get supplied on the first call:

```
call mg(j,uj,trerr=trerr)
```

The second and subsequent calls at a given level supply `rhs=tau` but omit `trerr`:

```
call mg(j-1,v,tau)
```

Note that we can omit the keyword `rhs` from this call because the variable `tau` appears in the correct order of arguments. However, in the other call above, the keyword `trerr` must be supplied because `rhs` has been omitted.

The example equation that is solved in `mgfas`, equation (19.6.44), is almost linear, and the code is set up so that ρ is supplied as part of the right-hand side instead of pulling it over to the left-hand side. The variable `rho` is visible to `mg` by host association. Note also that the function `lop` does not include `rho`, but that the statement

```
tau=lop(ut)-rstrct(lop(u))
```

is nevertheless correct, since `rho` would cancel out if it were included in `lop`. This feature is also true in the Fortran 77 code.

Chapter B20. Less-Numerical Algorithms

f90 Volume 1's Fortran 77 routine `machar` performed various clever con-
 tortions (due to Cody, Malcolm, and others) to discover the underlying
 properties of a machine's floating-point representation. Fortran 90, by
 contrast, provides a built-in set of "numeric inquiry functions" that accomplish the
 same goal. The routine `machar` included here makes use of these and is included
 largely for compatibility with the previous version.

```
SUBROUTINE machar(ibeta,it,irnd,ngrd,machep,negep,iexp,minexp,&
    maxexp,eps,epsneg,xmin,xmax)
USE nrtype
IMPLICIT NONE
INTEGER(I4B), INTENT(OUT) :: ibeta,iexp,irnd,it,machep,maxexp,minexp,negep,ngrd
REAL(SP), INTENT(OUT) :: eps,epsneg,xmax,xmin
REAL(SP), PARAMETER :: RX=1.0
```

Determines and returns machine-specific parameters affecting floating-point arithmetic. Re-
 turned values include `ibeta`, the floating-point radix; `it`, the number of base-`ibeta` digits
 in the floating-point mantissa; `eps`, the smallest positive number that, added to 1.0, is
 not equal to 1.0; `epsneg`, the smallest positive number that, subtracted from 1.0, is not
 equal to 1.0; `xmin`, the smallest representable positive number; and `xmax`, the largest rep-
 resentable positive number. See text for description of other returned parameters. Change
 all `REAL(SP)` declarations to `REAL(DP)` to find double-precision parameters.

```
REAL(SP) :: a,beta,betah,one,temp,tempa,two,zero
ibeta=radix(RX)
it=digits(RX)
machep=exponent(nearest(RX,RX)-RX)-1
negep=exponent(nearest(RX,-RX)-RX)-1
minexp=minexponent(RX)-1
maxexp=maxexponent(RX)
iexp=nint(log(real(maxexp-minexp+2,sp))/log(2.0_sp))
eps=real(ibeta,sp)**machep
epsneg=real(ibeta,sp)**negep
xmax=huge(RX)
xmin=tiny(RX)
one=RX
two=one+one
zero=one-one
beta=real(ibeta,sp)
a=beta**(-negep)
irnd=0
betah=beta/two
temp=a+betah
if (temp-a /= zero) irnd=1
tempa=a+beta
temp=tempa+betah
if ((irnd == 0) .and. (temp-tempa /= zero)) irnd=2
ngrd=0
```

Most of the parameters are easily determined
 from intrinsic functions.

Determine `irnd`.

Determine `ngrd`.

```

temp=one+eps
if ((irnd == 0) .and. (temp*one-one /= zero)) ngrd=1
temp=xmin/two
if (temp /= zero) irnd=irnd+3           Adjust irnd to reflect partial underflow.
END SUBROUTINE machar

```

* * *

```

FUNCTION igray(n,is)

ch=char(i+48)
END FUNCTION decchk

```

Look at successive characters.

Ignore everything except digits.

Find which appended digit will check properly.

Convert to ASCII.

Note the use of the utility function `ifirstloc` to find the first (in this case, the only) correct check digit.

* * *

The Huffman and arithmetic coding routines exemplify the use of modules to encapsulate user-defined data types. In these algorithms, “the code” is a fairly complicated construct containing scalar and array data. We define types `huffcode` and `arithcode`, then can pass “the code” from the routine that constructs it to the routine that uses it as a single variable.

```

C1. Listing of Utility Modules (nrtype and nrutil)

C1.1 Numerical Recipes Types (nrtype)

The file supplied as `nrtype.f90` contains a single module named `nrtype`, which in turn contains definitions for a number of named constants (that is, `PARAMETER`s), and a couple of elementary derived data types used by the sparse matrix routines in this book. Of the named constants, by far the most important are those that define the `KIND` types of virtually all the variables used in this book: `I4B`, `I2B`, and `I1B` for integer variables, `SP` and `DP` for real variables (and `SPC` and `DPC` for the corresponding complex cases), and `LGT` for the default logical type.

MODULE nrtype

Symbolic names for kind types of 4-, 2-, and 1-byte integers:

```
INTEGER, PARAMETER :: I4B = SELECTED_INT_KIND(9)
INTEGER, PARAMETER :: I2B = SELECTED_INT_KIND(4)
INTEGER, PARAMETER :: I1B = SELECTED_INT_KIND(2)
```

Symbolic names for kind types of single- and double-precision reals:

```
INTEGER, PARAMETER :: SP = KIND(1.0)
INTEGER, PARAMETER :: DP = KIND(1.0D0)
```

Symbolic names for kind types of single- and double-precision complex:

```
INTEGER, PARAMETER :: SPC = KIND((1.0,1.0))
INTEGER, PARAMETER :: DPC = KIND((1.0D0,1.0D0))
```

Symbolic name for kind type of default logical:

```
INTEGER, PARAMETER :: LGT = KIND(.true.)
```

Frequently used mathematical constants (with precision to spare):

```
REAL(SP), PARAMETER :: PI=3.141592653589793238462643383279502884197_sp
REAL(SP), PARAMETER :: PI02=1.57079632679489661923132169163975144209858_sp
REAL(SP), PARAMETER :: TWOPI=6.283185307179586476925286766559005768394_sp
REAL(SP), PARAMETER :: SQRT2=1.41421356237309504880168872420969807856967_sp
REAL(SP), PARAMETER :: EULER=0.5772156649015328606065120900824024310422_sp
REAL(DP), PARAMETER :: PI_D=3.141592653589793238462643383279502884197_dp
REAL(DP), PARAMETER :: PI02_D=1.57079632679489661923132169163975144209858_dp
REAL(DP), PARAMETER :: TWOPI_D=6.283185307179586476925286766559005768394_dp
```

Derived data types for sparse matrices, single and double precision (see use in Chapter B2):

```
TYPE sprs2_sp
  INTEGER(I4B) :: n,len
  REAL(SP), DIMENSION(:), POINTER :: val
  INTEGER(I4B), DIMENSION(:), POINTER :: irow
  INTEGER(I4B), DIMENSION(:), POINTER :: jcol
END TYPE sprs2_sp
TYPE sprs2_dp
  INTEGER(I4B) :: n,len
  REAL(DP), DIMENSION(:), POINTER :: val
```

```

    INTEGER(I4B), DIMENSION(:), POINTER :: irow
    INTEGER(I4B), DIMENSION(:), POINTER :: jcol
END TYPE sprs2_dp
END MODULE nrtype

```

About Converting to Higher Precision

You might hope that changing all the Numerical Recipes routines from single precision to double precision would be as simple as redefining the values of SP and DP in *nrtype*. Well ... not quite.

Converting algorithms to a higher precision is not a purely mechanical task because of the distinction between “roundoff error” and “truncation error.” (Please see Volume 1, §1.2, if you are not familiar with these concepts.) While increasing the precision implied by the kind values SP and DP will indeed reduce a routine’s roundoff error, it will not reduce any truncation error that may be intrinsic to the algorithm. Sometimes, a routine contains “accuracy parameters” that can be adjusted to reduce the truncation error to the new, desired level. In other cases, however, the truncation error cannot be so easily reduced; then, a whole new algorithm is needed. Clearly such new algorithms are beyond the scope of a simple mechanical “conversion.”

If, despite these cautionary words, you want to proceed with converting some routines to a higher precision, here are some hints:

If your machine has a kind type that is distinct from, and has equal or greater precision than, the kind type that we use for DP, then, in *nrtype*, you can simply redefine DP to this new highest precision and redefine SP to what was previously DP. For example, DEC machines usually have a “quadruple precision” real type available, which can be used in this way. You should not need to make any further edits of *nrtype* or *nrutil*.

If, on the other hand, the kind type that we already use for DP is the highest precision available, then you must leave DP defined as it is, and redefine SP in *nrtype* to be this same kind type. Now, however, you will also have to edit *nrutil*, because some overloaded routines that were previously distinguishable (by the different kind types) will now be seen by the compiler as indistinguishable — and it will object strenuously. Simply delete all the “_dp” function names from the list of overloaded procedures (i.e., from the MODULE PROCEDURE statements). Note that it is not necessary to delete the routines from the MODULE itself. Similarly, in the interface file *nr.f90* you must delete the “_dp” interfaces, *except* for the *sprs...* routines. (Since they have TYPE(*sprs2_dp*) or TYPE(*sprs2_sp*), they are treated as distinct even though they have functionally equivalent kind types.)

Finally, the following table gives some suggestions for changing the accuracy parameters, or constants, in some of the routines. Please note that this table is not necessarily complete, and that higher-precision performance is not guaranteed for all the routines, *even if* you make all the changes indicated. The above edits, and these suggestions, do, however, work in the majority of cases.

C1.2 Numerical Recipes Utilities (nrutil)

The file supplied as `nrutil.f90` contains a single module named `nrutil`, which contains specific implementations for all the Numerical Recipes utility functions described in detail in Chapter 23.

The specific implementations given are something of a compromise between demonstrating parallel techniques (when they can be achieved in Fortran 90) and running efficiently on conventional, serial machines. The parameters at the beginning of the module (names beginning with `NPAR_`) are typically related to array lengths *below which* the implementations revert to serial operations. On a purely serial machine, these can be set to large values to suppress many parallel constructions.

The length and repetitiveness of the `nrutil.f90` file stems in large part from its extensive use of overloading. Indeed, the file would be even longer if we overloaded versions for all the applicable data types that each utility could, in principle, instantiate. The descriptions in Chapter 23 detail both the full set of intended data types and shapes for each routine, and also the types and shapes actually here implemented (which can also be gleaned by examining the file). The intended result of all this overloading is, in essence, to give the utility routines the desirable properties of many of the Fortran 90 intrinsic functions, namely, to be both *generic* (apply to many data types) and *elemental* (apply element-by-element to arbitrary shapes). Fortran 95's provision of user-defined elemental functions will reduce the multiplicity of overloading in some of our routines; unfortunately the necessity to overload for multiple data types will still be present.

Finally, it is worth reemphasizing the following point, already made in Chapter 23: The purpose of the `nrutil` utilities is to remove from the Numerical Recipes programs just those programming tasks and "idioms" whose efficient implementation is *most* hardware and compiler dependent, so as to allow for specific, efficient implementations on different machines. One should therefore not expect the utmost in efficiency from the general purpose, one-size-fits-all, implementation listed here.

Correspondingly, we would encourage the incorporation of efficient `nrutil` implementations, and/or comparable capabilities under different names, with as broad as possible a set of overloaded data types, in libraries associated with specific compilers or machines. In support of this goal, we have specifically put this Appendix C1, and the files `nrtype.f90` and `nrutil.f90`, into the public domain.

MODULE `nrutil`

TABLE OF CONTENTS OF THE NRUTIL MODULE:

- routines that move data:
 - `array_copy`, `swap`, `reallocate`
- routines returning a location as an integer value
 - `ifirstloc`, `imaxloc`, `iminloc`
- routines for argument checking and error handling:
 - `assert`, `assert_eq`, `nrerror`
- routines relating to polynomials and recurrences
 - `arth`, `geop`, `cumsum`, `cumprod`, `poly`, `polyterm`, `zroots_unity`
- routines for "outer" operations on vectors
 - `outerand`, `outersum`, `outerdiff`, `outerprod`, `outerdiv`
- routines for scatter-with-combine
 - `scatter_add`, `scatter_max`
- routines for skew operations on matrices
 - `diagadd`, `diagmult`, `get_diag`, `put_diag`,

```

        unit_matrix, lower_triangle, upper_triangle
        miscellaneous routines
        vabs
USE nrtype
    Parameters for crossover from serial to parallel algorithms (these are used only within this
    nrutil module):
IMPLICIT NONE
INTEGER(I4B), PARAMETER :: NPAR_ARTH=16,NPAR2_ARTH=8      Each NPAR2 must be ≤ the
INTEGER(I4B), PARAMETER :: NPAR_GEOP=4,NPAR2_GEOP=2        corresponding NPAR.
INTEGER(I4B), PARAMETER :: NPAR_CUMSUM=16
INTEGER(I4B), PARAMETER :: NPAR_CUMPROD=8
INTEGER(I4B), PARAMETER :: NPAR_POLY=8
INTEGER(I4B), PARAMETER :: NPAR_POLYTERM=8
    Next, generic interfaces for routines with overloaded versions. Naming conventions for ap-
    pendiced codes in the names of overloaded routines are as follows: r=real, d=double pre-
    cision, i=integer, c=complex, z=double-precision complex, h=character, l=logical. Any of
    r,d,i,c,z,h,l may be followed by v=vector or m=matrix (v,m suffixes are used only when
    needed to resolve ambiguities).
    Routines that move data:
INTERFACE array_copy
    MODULE PROCEDURE array_copy_r, array_copy_d, array_copy_i
END INTERFACE
INTERFACE swap
    MODULE PROCEDURE swap_i,swap_r,swap_rv,swap_c, &
        swap_cv,swap_cm,swap_z,swap_zv,swap_zm, &
        masked_swap_rs,masked_swap_rv,masked_swap_rm
END INTERFACE
INTERFACE reallocate
    MODULE PROCEDURE reallocate_rv,reallocate_rm,&
        reallocate_iv,reallocate_im,reallocate_hv
END INTERFACE
    Routines returning a location as an integer value (ifstloc, iminloc are not currently over-
    loaded and so do not have a generic interface here):
INTERFACE imaxloc
    MODULE PROCEDURE imaxloc_r,imaxloc_i
END INTERFACE
    Routines for argument checking and error handling (nrerror is not currently overloaded):
INTERFACE assert
    MODULE PROCEDURE assert1,assert2,assert3,assert4,assert_v
END INTERFACE
INTERFACE assert_eq
    MODULE PROCEDURE assert_eq2,assert_eq3,assert_eq4,assert_eqn
END INTERFACE
    Routines relating to polynomials and recurrences (cumprod, zroots_unity are not currently
    overloaded):
INTERFACE arth
    MODULE PROCEDURE arth_r, arth_d, arth_i
END INTERFACE
INTERFACE geop
    MODULE PROCEDURE geop_r, geop_d, geop_i, geop_c, geop_dv
END INTERFACE
INTERFACE cumsum
    MODULE PROCEDURE cumsum_r,cumsum_i
END INTERFACE
INTERFACE poly
    MODULE PROCEDURE poly_rr,poly_rrv,poly_dd,poly_ddv,&
        poly_rc,poly_cc,poly_msk_rrv,poly_msk_ddv
END INTERFACE
INTERFACE poly_term
    MODULE PROCEDURE poly_term_rr,poly_term_cc
END INTERFACE
    Routines for "outer" operations on vectors (outerand, outersum, outerdiv are not currently
    overloaded):
INTERFACE outerprod

```

```

MODULE PROCEDURE outerprod_r,outerprod_d
END INTERFACE
INTERFACE outerdiff
MODULE PROCEDURE outerdiff_r,outerdiff_d,outerdiff_i
END INTERFACE
Routines for scatter-with-combine, scatter_add, scatter_max:
INTERFACE scatter_add
MODULE PROCEDURE scatter_add_r,scatter_add_d
END INTERFACE
INTERFACE scatter_max
MODULE PROCEDURE scatter_max_r,scatter_max_d
END INTERFACE
Routines for skew operations on matrices (unit_matrix, lower_triangle, upper_triangle not
currently overloaded):
INTERFACE diagadd
MODULE PROCEDURE diagadd_rv,diagadd_r
END INTERFACE
INTERFACE diagmult
MODULE PROCEDURE diagmult_rv,diagmult_r
END INTERFACE
INTERFACE get_diag
MODULE PROCEDURE get_diag_rv, get_diag_dv
END INTERFACE
INTERFACE put_diag
MODULE PROCEDURE put_diag_rv, put_diag_r
END INTERFACE
Other routines (vabs is not currently overloaded):
CONTAINS

Routines that move data:
SUBROUTINE array_copy_r(src,dest,n_copied,n_not_copied)
Copy array where size of source not known in advance.

```

C2. Alphabetical Listing of Explicit Interfaces

The file supplied as `nr.f90` contains explicit interfaces for all the Numerical Recipes routines (except those already in the module `nrutil`). The interfaces are in alphabetical order, by the generic interface name, if one exists, or by the specific routine name if there is no generic name.

The file `nr.f90` is normally invoked via a `USE` statement within a main program or subroutine that references a Numerical Recipes routine. See §21.1 for an example.

C3. Index of Programs and Dependencies

The following table lists, in alphabetical order, all the routines in Volume 2 of *Numerical Recipes*. When a routine requires subsidiary routines, either from this book or else user-supplied, the full dependency tree is shown: A routine calls directly all routines to which it is connected by a solid line in the column immediately to its right; it calls indirectly the connected routines in all columns to its right. Typographical conventions: Routines from this book are in typewriter font (e.g., `eulsum`, *gamm1n*). The smaller, slanted font is used for the second and subsequent occurrences of a routine in a single dependency tree. (When you are getting routines from the *Numerical Recipes* machine-readable media or hypertext archives, you need specify names only in the larger, upright font.) User-supplied routines are indicated by the use of text font and square brackets, e.g., `[funcv]`. Consult the text for individual specifications of these routines. The right-hand side of the table lists chapter and page numbers for each program.

General Index to Volumes 1 and 2

In this index, page numbers 1 through 934 refer to Volume 1, *Numerical Recipes in Fortran 77*, while page numbers 935 through 1446 refer to Volume 2, *Numerical Recipes in Fortran 90*. Front matter in Volume 1 is indicated by page numbers in the range 1/i through 1/xxxi, while front matter in Volume 2 is indicated 2/i through 2/xx.
