ABSTRACT

Despite the devastating impact that flooding, drought and fire associated with the 1982/3 and 1997/8 El Niño events had on both the natural environment and human society, there is little information on the persistence or impact similar events may have had in the ‘deeper’ past. Palaeoecologists can offer insight into the nature of environmental change over a range of spatiotemporal scales, utilising high-resolution techniques that can broaden the interpretation of issues that are specifically relevant to historians, geographers and anthropologists. In some cases there appears to be a correspondence between major climatic events and a change in cultural development that leads us to ask the question, ‘How significant has climate change been in the development of human society?’ We discuss the role of environmental history in studies of cultural change, and critically assess four case studies where climate may have had a significant impact on the development of human society: human evolution in Africa, development of agriculture in New Guinea, urban collapse in Central and South America, and Pacific island occupation.

Climate change, El Niño, palaeoecology, archaeology, agriculture
INTRODUCTION

Despite the devastating impact that flooding, drought and fire associated with the 1982/3 and 1997/8 El Niño events had on both the natural environment and human society, there is little information on the impact similar events may have had in the deeper past. Historians and archaeologists have documented catastrophic events in human history from the collapse of great civilisations to the rise of devastating pandemics, which suggest human history has been influenced by extreme events and non-linear processes, many of which we know little about.

The environmental impacts of recent major El Niño events have focussed attention on the impact of extreme climatic events on modern cultures and raised again the question, ‘How significant has climate change been in the development of human society?’ The anthropological perspective of human cultures is mostly synchronic, only rarely turning to historical or prehistorical data as a means of understanding contemporary indigenous cultures. Headland points out that ignorance of the influence of past environmental changes on present-day cultures has led to the prolonged acceptance of the idea that with the utilisation of fire and the development of agriculture, human communities became the exploiters of nature. Historical ecologists, defined as those who study past ecosystems by charting the change in landscapes over time, have emphasised that the dichotomy between ‘natural’ and human-influenced landscapes is a false one and that ecosystems have not only been greatly modified by humans for thousands of years, but also that natural processes have played a part in modifying human societies over this same time period. Such an historico-ecological approach makes one major prediction: that the fate of a society will be determined by the ecology of the land in which it exists. This is not to say that the traditional notion of environmental determinism is validated—that a region’s natural surroundings decide the kind of culture found there. Rather, it proposes that the environment sets certain constraints on what any population can achieve within a given technology, and that natural environmental variation may play a role in changing the course of cultural development, agricultural development being, at least in part, climatically determined. The changes in climate, resources and habitats are not simply background information overlain by cultural change, but are considered a continually changing set of problems and opportunities altering the context for human survival. This approach challenges historical convention by the attention it gives to non-human agents in cultural transformation.

To test this hypothesis requires the data on societal and environmental transformations to have high chronological precision. This is not readily achieved, given that sites containing evidence for human activity may be geographically some distance from sites containing evidence for environmental change. In addition, just because there might be a correlation between a climate event and a change in human society does not prove a causal link. Especially in cases where chronological control is poor, it is difficult to determine coincidence let alone
CAN CLIMATE INFLUENCE CULTURAL DEVELOPMENT?

FIGURE 1. Major events in human evolution are compared with our knowledge of global climate change. Deep sea cores have provided a continuous record of global climatic change from (a) the ratio of the different natural isotopes of oxygen, $^{16}O$ and $^{18}O$, in the shells of the benthic foraminifera provides a proxy of global temperature (Ocean Drilling Project Site 659), and (b) magnetic susceptibility is a proxy for the amount of icebergs in the North Pacific Ocean, which can only occur when there are large ice sheets on the Northern Hemisphere (Ocean Drilling Project Site 882). Using these proxy indicators of climate change preserved in deep ocean sediments the global climate appears to have begun to change from hot and wet at 3.2 million years ago to cold and dry by the middle Pliocene at about 2.6 million years ago. This was reflected by the gradual build up of ice in both the Arctic and Antarctic. The dramatic increase in the magnetic susceptibility from the North Pacific at 2.6 million years ago indicates that there was for the first time significant amounts of ice in the Arctic and on North America. After this, the global climate cycles appear to have intensified, varying from very cold glacial with huge ice sheets covering much of North America and Northern Europe, to interglacials with climate comparable to the present (adapted from Maslin 1996).
cause and effect. An example of this problem can be illustrated in a recent debate on the causes for human evolution over the last 5 million years. Some researchers have speculated that the global cooling and the subsequent drying of Africa was the driving force behind the evolution of *Homo* (Fig. 1). Furthermore, as the local climate became drier the vegetation became more open and hardier, this would have prompting the evolution of a species i.e. *Homo*, which was more mobile and had a more omnivore diet. The development of society itself is also touted as a possible driving force behind early human evolution. In this case, it remains impossible to test the hypothesis because of the inability to replicate the experiment. This is not the case in later history, when human populations spread across the globe and became geographically and culturally isolated from one another, though subject to the same global climate phenomena.

The approach advocated here to compare historico-ecological records from separate regions, allowing us to test if a similar cultural response results from a given climatic event. We present three case studies that illustrate (1) the impact of natural catastrophic and non-linear processes on the development of human society, and (2) the adaptations made by these societies to these events and processes. These examples cross a wide range of spatial and temporal scales, though in each case there appears to be a correspondence between a major climatic (or volcanic) event and a change in cultural development in more than one geographically separated areas: the development of agriculture, the vulnerability of wetland agricultural communities and sustainability of isolated island settlements.

**DEVELOPMENT OF AGRICULTURE: THE HIGHLAND NEW GUINEA CASE**

An examination of the palynological and archaeological evidence for the earliest shifts from hunting and gathering strategies to agriculture shows a striking synchronism in a number of separate regions around the globe around 10,000 years ago. That this significant shift in cultural adaptation should occur at the end of a period of great climatic change, when forests had largely replaced grasslands and the climate was warmer and in many cases wetter, may point to agricultural development being climatically determined. The investigation of this hypothesis is perhaps best developed in more temperate regions such as the Near East where multiple sites and detailed genetic research on cereal crops have shown that highly seasonal climates at the end of the last glacial strongly selected for the ancestral domesticate plants. Another example comes from northern China where plant domestication is considered to be well underway by 10,000 yr BP in a favourable steppe-forest or forested environment that underwent a rapid climatic transformation towards steppe-like conditions at this time, forcing selection of specific plants to sustain subsistence in a rapidly changing environ-
CAN CLIMATE INFLUENCE CULTURAL DEVELOPMENT?

ment. Certainly, in view of the different crops that have been domesticated in each area it seems likely that the development of agriculture was independent within each region and not diffused from a single centre, refuting the earlier diffusionists ideas.¹⁴

When agriculture developed in New Guinea has long been debated.¹⁵ The primary source of evidence for all these discussions comes from Kuk swamp where a 9000 year old sequence of swamp drainage and concomitant dryland exploitation for food production is claimed. This represents the earliest archaeological indication that subsistence strategies for highlands populations had reached a stage where parts of the environment were being manipulated for food production. However, there is fragmentary evidence that suggests human manipulation of plant communities may be an important factor as early as 30,000 yr BP, supporting the idea of a gradual increase in environmental manipulation for at least 20,000 years prior to the first archaeological evidence for agriculture around 9000 yr BP.¹⁸ The maintenance of grasslands in the valley floors by fire from as early as 21,000 yr BP through to at least 9000 yr BP and an intensification of burning between 14,500 and 12,000 yr BP in the Tari Basin suggest sustained exploitation of food plants in the highlands may have occurred some 3000-5000 years before the evidence at Kuk.

The record of climate change and archaeological evidence for agriculture in the highlands of New Guinea over the last 20,000 years is compared in Figure 2. Climatic amelioration begins soon after the last glacial maximum, though climatic variability remains high, with infrequent but severe droughts characterising the highland valleys between 16,000–12,000 yr BP. The transition from last glacial to present interglacial climates is finally achieved over a rapid transition period of at most 1000 years from 10,000 to 9000 yr BP. There are no clear indications of climate change during the present interglacial, but increased disturbance during the last 5000 years, and particularly within the last 2000 years, may be partly related to increased climatic variability brought on by the influence of El Niño-Southern Oscillation (ENSO)-type events.

These climate changes appear to coincide with shifts in subsistence strategies recorded in the archaeological record, particularly the proposed development of agriculture around 9000 yr BP at a time of rapid climate change. If agriculture developed in the highland valleys at this time, then what plants were being exploited? Figure 3 shows that, although a number of food species are clearly excluded from the highlands during colder periods, including tubers and fruits like yams and bananas important in traditional New Guinea agriculture, nevertheless a range of vegetable foods which are recorded as cultivated in modern gardens may have been viable in highlands valleys and basins. These included traditionally important cultigens like taro, sugar cane and gourd, if these were in fact present in the island at this date. It is important to keep in mind some obvious shortcomings to any argument that assumes the presence of these plants in the highlands before human habitation. The three crops mentioned above and many
FIGURE 2 (above). Climate change in New Guinea is compared with phases of wetland agricultural activity recorded at Kuk Swamp archaeological site. A possible model for the development of agriculture in the highlands of New Guinea from 20,000 yr BP through to the present is given on the right of the diagram.

FIGURE 3 (opposite). The present day and last glacial maximum vegetation distributions in New Guinea are shown with the distribution of a number of important, and potentially important, food plants. Present day distributions are compared with those that would have been likely with a theoretical reduction of vegetation zones of 850–1500 m at the height of the last glacial maximum due to cooler temperatures: the highest level at which a species might be found. Taxa considered viable crops in the highlands during glacial climates occur above an altitude of 1200 m, the lower limit of highland valleys.
CAN CLIMATE INFLUENCE CULTURAL DEVELOPMENT?
of the plants listed in Figure 3 may in fact be ancient introductions to the island of New Guinea with their range having been extended by early agriculturalists (e.g. *Colocasia esculenta*; *Lagenaria*; *Saccharum officinarum* lowlands domesticate; *Dioscorea alata* and *Musa* ‘diploid’ Southeast Asian introductions). In addition it should be appreciated, of course, that the limits quoted for these plants in Figure 3 are those under an agricultural regime many millennia old, so that the ‘original’ limits are unknown, and the same may apply to other entries in the figure.

Limitations on plant growth extend beyond the simple matter of temperature; other factors such as frost severity and cloudiness must be considered as limiting conditions for cultivation. As regards the former, in well-protected garden areas where plants can be shaded by taller trees like *Pandanus* or ring-barked forest trees, the flow of cold air that may result in frost damage is generally slight. As regards cloudiness, persistent cloud may not necessarily be evenly spread through a last glacial mountain valley, due to topographic barriers and the presence of open grasslands locally reducing cloud formation. The occurrence of infrequent but severe droughts and associated frost between 16,000 and 12,000 yr BP in the Tari Basin, central highlands of New Guinea, would have put sustained production of most food plants out of question, but short-term and sporadic production would have been possible in this environment. Limited and localised as forest clearances for such purposes may have been, they would have added to other benefits of extending open vegetation for hunting and ease of communication.

A suite of tuber, vegetable and nut crops is considered on the evidence of Figure 3 to have been candidates for successful cultivation in this environment, though we have direct evidence in the record only for the nut-producing genus *Pandanus*. This proposition gives a much fuller context for the 9000 yr BP cultivation system claimed for Kuk, where the specification of what was being grown has always been imprecise, though invariably considered to be plants brought up from lower altitudes in pace with climatic amelioration. In his most recent statement Golson uses Yen’s conclusions about cultigens of putatively New Guinea origin to suggest that planting at Kuk could have included bananas, sugar cane, probably yams and possibly taro, which he sees as having first been taken into cultivation under more benign conditions within the *Castanopsis/Lithocarpus* forests of lower altitudes. Gorecki also proposes that agriculture had its origins earlier and at lower altitudes than Kuk. However, since, as we have seen, the altitudinal extremes of some of the plants cultivated in traditional New Guinea systems were within the highlands valleys during the last glacial, where conditions for their growth would have been more susceptible to change than at lower altitudes, it is worth considering climatic change at the ‘edge of the range’ of crop viability as a major factor in shifting strategies of food production in the light of other evidence for agricultural activity throughout the tropical (and temperate) world.
In the New Guinea highlands situation subsistence strategies for managing plant food resources had been developed in the highlands under a cold, highly variable environment subject to severe drought stress between 16,000 and 12,000 yr BP. These effective strategies, operating at the ‘edge of the range’ for a number of important plant types, were able to be intensified under the onset of rapidly ameliorating climates less subject to stress across the highlands between 12,000 and 9000 yr BP. At the same time there would have been less pressure to develop effective planting strategies at the centre of growth range for most plants, that is at lower altitude. Though this is a hypothesis needing fuller substantiation, it does not appear necessary any longer to situate agricultural origins in New Guinea, as has been regularly done, in the lower altitudes of the highlands fringes, with subsequent transplantation of plants and techniques into the highlands valleys.

VULNERABILITY OF WETLAND AGRICULTURE

Climate changes are generally considered to be relatively minor during the last 10,000 years, though it has been suggested that the impact of short-term climate variability, such as increased drought stress associated with ENSO events, has had a significant influence on vegetation dynamics in the Pacific region over the last five to three millennia. This has been supported further by records showing landscape destabilisation around 5000 yr BP from the South American coast and increased disturbance of vegetation in Australia and New Guinea between 5000 and 4000 years ago.

In a study of the Mayan settlement, Hodell and others show that cultural development and population expansion occurred under conditions favourable to agriculture and that the decline of the Maya cultures were associated with protracted and severe droughts. A similar sequence of cultural change is linked to the failure of wetland agricultural systems in the Bolivian altiplano at Tiwanaku around 850 cal yr BP when low lake levels reflect a period of protracted dry climate. Meggers has also suggested that synchronous discontinuities in archaeological sequences of human occupation in the lowland rainforests of Amazonia are related to ‘mega-Niño’ events centred around dates of 1350, 950, 650 and 500 cal yr BP. These studies suggest that there are climatic thresholds for cultural development and that abrupt, unpredictable climate changes can have devastating consequences on human populations by disrupting agricultural production forcing repeated human dispersal or realignment of social and trade networks.

A proxy record of the climate for the last 2000 cal yr BP in equatorial Andes of South America (Figure 4) comes from ice core and lake level records in the Peruvian Andes. The occurrence of major dry or wet events are likely to be synchronous across the equatorial Pacific transect to New Guinea due to physical
connection through the Walker Circulation. If the Peruvian drought record does coincide with drought in highland New Guinea, as suggested by limited tree-ring and historical records from Java and Peru, then the highlands of New Guinea may have experienced severe and prolonged drought at the same time. The major dust events recorded in ice cores from Peru point to the possible occurrence of major El Niño-related droughts in highlands of Peru between 1100-900 cal yr BP and between 1450-1200 cal yr BP (Fig. 4). The possibility that small-scale climate change had a significant impact on prehistoric agriculture in the highlands of New Guinea is also considered by Brookfield, who suggests that the abandonment and re-use of Kuk Swamp in the highlands of

FIGURE 4. Natural causes of cultural change in equatorial Americas and New Guinea. A series of climate proxy records (temperature from Huascaran ice core δ¹⁸O record, drought periods from Quelcaya ice core dust particles >1.59 µm, a composite time series for the recurrence of El Niño events since 1000 cal yr BP and the occurrence of the Little Ice Age and Medieval Warm Epoch) from equatorial South America and archaeological
Papua New Guinea may be linked to periods of greater or lesser climate variability. As yet, the palaeoecological record from New Guinea does not have the resolution of the annually laminated ice cores of Peru, so if these event did occur in the past, they are not visible in the available records.

Comparison of the available palaeoenvironmental data from New Guinea with the equatorial American record shows a striking synchrony between apparent low climatic variability during the Medieval Warm Period and the absence of swamp agriculture at Kuk (Fig. 4). Swamp cultivation appears to occur during periods of greatest climatic variability. Periods of chronic drought stress may have initiated the need for greater ground-water control leading to the

---

phases from the Yucatan lowlands (Maya\textsuperscript{52}) and the Bolivian altiplano (Tiwanaku;\textsuperscript{53} Alnus agroforestry\textsuperscript{54}) are compared with inferred climate and cultural changes in highland New Guinea over the last 2000 cal yr BP. Kuk swamp agricultural phases and the development of Casuarina agroforestry\textsuperscript{55} show the switching from wetland to dryland agriculture under the influence of tephra impact and climate change.
development of grid patterns of field ditches, seen in Phase 4 and onwards at Kuk swamp. Long-term anthropogenic landscape change, notably forest clearance and land degradation before 1190-970 cal yr BP, has been implicated in the adoption of widespread *Casuarina* planting as an agroforestry tree. A similar feature appears to have been recorded in the highlands of Peru, where pollen records show that *Alnus* was possibly planted widely as a dryland agroforestry tree after 850 cal yr BP. Both *Casuarina* and *Alnus* are nitrogen-fixing trees used in traditional agroforestry systems that have played a significant role in sustaining human populations in a variety of tropical soil and climate conditions, and may have been adopted as a response to low crop productivity and the need to rehabilitate abandoned dryland crop lands after prolonged climatic stress.

**SUSTAINABILITY OF PACIFIC ISLAND SOCIETIES**

The prehistory of human colonisation across the Pacific is relatively well known, providing information on the chronology for the presence and absence of humans in the region. Figure 5 shows the progression of human populations from

![FIGURE 5. Location of Easter Island (Ea). The age of human colonisation eastwards into the Pacific Ocean is depicted by schematic lines of initial habitation from archaeological data.](image)
Asia eastward across the Pacific. The islands west of the Bismark Archipelago have been occupied by humans for at least the last 28,000 years. The initial phase of Polynesian migration eastwards into the central and eastern Pacific, including Fiji, only began in earnest after about 3500 yr BP, some 1500 years after the proposed enhancement of Holocene ENSO variability. The eastern and southwestern islands of this region, such as Hawai‘i, Cook Islands, New Zealand and Easter Island, were the last to receive Polynesian settlers, possibly within the last 1200 cal yr BP, though the exact timing of this final expansion is a matter of debate.

Prehistoric human impacts on the environment of Pacific islands to the west of Easter Island have been well documented in palaeoecological and archaeological studies, that include evidence for major forest clearance, increased

FIGURE 6. A diagrammatic model of some of the historical events and main trends in environmental change on Easter Island compared with trends in climate change across the Pacific (time series for the recurrence of El Niño events since 1000 cal yr BP and the occurrence of the Little Ice Age and Medieval Warm Epoch; volcanic eruptions of the last 550 cal yr BP causing global cooling).
erosion on hillsides and alluvial deposition in valley bottoms, increased burning, introduction of exotic species and extinction of native species. However, the timing and nature of disturbance induced by Polynesian occupation is open to some debate due to the difficulties of separating human from natural processes of disturbance in the palaeoecological and archaeological records.67

Bahn and Flenley68 reduced the main trends of Easter Island ecological history to a few key proxy signals, and Figure 6 shows these with the addition of two new proxy climate signals for the Pacific: a composite time series for the recurrence of El Niño events compared to the global air temperature changes since 950 cal yr BP;69 and, known volcanic eruptions since 550 cal yr BP causing anomalous global cooling of up to 1°C.70 There is a striking correspondence between the period of statue building, the most resource demanding phase of human occupation, and the phase of low ENSO activity. Similarly, the cause of the ultimate collapse of the society that made these statues around 180 cal yr BP appears to be closely linked to a period of intense ENSO activity, coupled with frequent volcanic disruption to global climate. It has been suggested that the impact of the activities of the early human settlers was the major factor that led to the eventual collapse of island society around 180 cal yr BP (1770 AD).71 The island had certainly undergone substantial deforestation since initial settlement,72 but the alternative explanation may be that the environmental outcomes of a prolonged period of severe droughts and cooler global temperatures during the 17th century, may have been sufficient, together with land degradation, to topple the existing society. However, this outcome of human occupation and land degradation on island communities was clearly not the case on all Pacific islands. Kirch illustrates the results of prolonged environmental degradation on two other Pacific islands, Mangaia and Tikopia, in which the adaptations made by these two communities led to completely different outcomes; sustainable production on Tikopia and depopulation/warfare on Mangaia.73

DISCUSSION

The evidence presented here of climate-culture interactions in several regions of the globe suggests a significant environmental component in human behaviour. Moreover there are numerous examples in the deep past of conflict over resources, episodes of environmental degradation, deforestation, soil erosion and extinctions. Around 10,000 years ago, something happened in at least three independent regions around the globe (China, Middle East, and highland New Guinea) which brought on a shift in plant resource exploitation that became agriculture. Similarly, around 1000–850 years ago in the tropics of the Americas and in the highlands of New Guinea, the breakdown of reliable wetland agricultural systems that had supported populations for centuries collapsed and resulted in a shift to dryland agriculture with a new agroforestry technology
CAN CLIMATE INFLUENCE CULTURAL DEVELOPMENT?

(Casuarina and Alnus) to alleviate nutrient depletion in the environment. A range of interrelated factors including population growth, environmental degradation, expanding exchange networks and increased inter-community warfare may have been implicated in the process; however, the rapid climate changes recorded globally at these times may have provided the impetus or even the necessity to alter the way resources were managed. That these changes are not always synchronous around the globe may be explained in terms of the relative vulnerability of ‘marginal’ populations to changes in climate.

Human cultures adapt to changing environmental conditions within a range of ‘normal’ environmental variability. An important ecological question for Homo sapiens is, at what point does the low frequency variation with larger amplitude exceed the limits of human adaptability? That limits exist is illustrated in the examples given here; however, quantification of this remains unanswered and will require sophisticated population dynamics models that incorporate climatic variability as well as social factors. This question may best be answered in Pacific island ecosystems, where dispersed populations inhabiting islands with different resources are subject to similar environmental variability, namely, the ENSO phenomenon with its strongest signature located across the tropical Pacific ocean, which is one of the best understood and predictable components of the global climate system. The environmental stresses that led to the demise of Easter Island society around 200 years ago appear to have included a strong climate change component, though this change may have had different outcomes on other Pacific islands.74

As to the implications of this kind of comparative research, Overpeck suggests that climate events of the type apparent in the present interglacial climate record may be our biggest concern in the years to come.75 Certainly, without the knowledge of natural long-term climate variations, no informed judgement can be made about the recent record of climatic changes, extremes of droughts, floods, storm frequencies, or changes in oceanic circulation. Extreme climatic events, by their infrequent nature, are difficult to evaluate or forecast unless pre-historical records are extended to reveal the frequency of prior occurrences. The historical ecology approach provides a means of tackling this question in and across geographically and socially separate regions. Knowledge of climatic change can aid in planning for possible shifts in temperature and precipitation: this knowledge is vital for anticipating the extent and impact of global climate change on human society.

NOTES

This paper was initially presented by the first author as a seminar in the Resource Management in Asia-Pacific Seminar Series, Research School of Pacific and Asian Studies, Australian National University in June 1998 while he was a Visiting Fellow at
the Department of Archaeology and Natural History in the same School. The authors would like to thank Jim Allen, Chris Ballard, Keith Bennett, Richard Grove and Geoff Hope for critical discussions and encouragement during the writing of this paper. Mark Maslin and Michael Bourke provided useful data. The authors were generously supported through the Ranieri-Jenkins Fund.

6 Dates and ages based on the radiocarbon method are given as uncalibrated radiocarbon years before AD 1950 (yr BP). Other dates are given as cal yr BP (calendar years before 1950 AD). This paper adopts the terms ‘glacial’ and ‘interglacial’ to refer to periods of low or high sea-level or relatively cold and warm climate during the Quaternary (last 2.6 million years), respectively. The oxygen isotope chronostatigraphy of Martinson et al. (1987) shows that the most recent cold phase peaks at around 18,000 yr BP, when sea-level was at its lowest, and is referred to here as the ‘last glacial maximum’. The ‘present interglacial’ began around 10,000 yr BP.
8 Leakey 1994.
10 The use of the term ‘highlands of New Guinea’ refers to the inland regions above an altitude of about 1200m and not exclusively to the present-day Highlands Provinces of Papua New Guinea.
