Intracranial Extra-osseous Chondroblastoma

Simulating Meningioma

Intracranial Extra-osseous Chondroblastoma

Simulating Meningioma
Abstract:

Extra-osseous chondroblastoma had been reported in different parts of the body, but not intracranially. We report a case of a pathologically-proven intracranial extra-osseous chondroblastoma of the right cavernous sinus in an 18 year old woman with computed tomography (CT), magnetic resonance (MR) and conventional angiographic features simulating meningioma.

INTRODUCTION:

Chondroblastoma is an uncommon benign cartilaginous bone tumor that typically occurs at the epiphysis of the long bones in the first two decades of life. When it occurs in older patients, chondroblastoma tends to involve unusual sites such as skull and pelvis (1,2). Although the majority of chondroblastoma remains non-aggressive and have a benign course, local recurrence, malignant transformation, and distant metastasis have all been documented (3-6). Few cases of osseous intracranial chondroblastoma involving the cranial bones have been reported (1, 2 ,7, 8,9,10). We report the first case of extra-osseous chondroblastoma occurring intracranially. The imaging features on computed
tomography (CT), magnetic resonance (MR), and conventional cerebral angiography were similar to meningioma.

**CASE REPORT:**

An 18-year-old woman was referred to our institution with four years history of generalized headache, and six months history of pain, blurring of vision, diplopia, and gradual proptosis of the right eye. Past medical history was unremarkable. Neurological examination revealed complete right third and fourth cranial nerves palsy with partial sixth nerve palsy. The right pupil was dilated, fixed and not reacting to light or accommodation directly or consensually. Fundoscopic examination revealed blurring of the medial aspect of the right optic disk and normal left optic disk. Contrast-enhanced brain CT examination showed a large enhancing right parasellar extra-axial mass with peripheral calcification, but no associated bone involvement [Fig.1]. Enhanced brain MR examination revealed a mass (4 x 5 x 4 cm) arising from the lateral wall of the right cavernous sinus encasing and displacing the right internal carotid artery medially and anteriorly. The mass has extended into the right optic canal and compressed the right optic nerve. On T2W images, the mass demonstrated predominantly intermediate signal intensity with the center showing mixed low and high signal intensity [Fig.2-A,B,C]. On T1W images, the mass demonstrated intermediate signal intensity with strong and homogenous enhancement, except for the center which failed to enhance [Fig.2-A,B,C]. Small enhancing dural tail was seen at the attachment with the dura. Signal void areas at the periphery of the mass were present corresponding to the calcifications seen on the CT. Conventional cerebral angiogram showed tumor blush in the right parasellar region.
in the early arterial phase with appearance similar to sun burst and late washout [Fig.3].

The tumor blood supply was derived mainly from the cavernous segment of the right internal carotid artery (ICA). The mass has compressed and narrowed the cavernous and suprasellar segments of the right ICA. The supraclinoid segment of the right ICA and the right middle cerebral artery were displaced posteriorly. Small nipple-shaped wide neck aneurysm arising from the anterior aspect of the supraclinoid segment of the right ICA was present. Branches of the right external carotid artery mainly the middle meningeal artery also contributed to the blood supply of the tumor.

A preoperative diagnosis of meningioma was made and right pterional craniotomy was performed. At surgery, heavily calcified hypervascular mass was found in the right middle cranial fossa adjacent to the greater wing of the sphenoid filling the right cavernous sinus. Almost total macroscopic excision was achieved and the aneurysm was wrapped with muscle and tissue. The patient had slow but steady uneventful postoperative recovery. There was no new focal neurological deficit apart from her known preoperative third, fourth, and sixth cranial nerves palsies. The histopathological examination of the tumor specimen revealed numerous multinucleated giant cells in a background of early calcifying chondroblasts, some of them are showing grooved nuclei. The findings were consistent with chondroblastoma. On follow up after three months from surgery, the patient's right orbital pain and diplopia had improved and the clinical examination showed complete recovery of the fourth and sixth cranial nerves palsies with persistent third cranial nerve palsy.
Discussion:

In 1928, Ewing first described the calcifying giant cell tumor, subsequently designated "epiphyseal chondromatous giant cell tumor" by Codman in 1931(11). The term chondroblastoma was introduced by Jaffe and Liechtenstein in 1942 (12). Although well recognized, chondroblastoma is still a rare tumor accounting for less than 1 % of all bone tumors(13). It involves the epiphysis of long bones in 97% of cases(2), predominantly occurs in the first two decades of life and boys are affected twice as often as girls(5, 7, 13). About 83% of chondroblastomas of the skull and face occur in patients over the age of 30 years, whilst 92% of chondroblastomas in long bones occur in patients less than 30 years of age(14,15). When chondroblastoma occurs in older patients, it tends to involve unusual sites like the skull and facial bones (14). The most common location of chondroblastoma involving cranial bones is the squamous portion of the temporal bone accounting for 70% of the cases (7,8). Extra-osseous chondroblastomas had been reported in the soft tissue of different parts of the body, but no previous reports had documented intracranial extra-osseous involvement. The majority of chondroblastomas remains non-aggressive and has a benign course. However, local recurrence, malignant transformation to sarcoma (often after radiotherapy), and distant metastasis have all been reported (3, 4, 5, 6).

Radiographically, chondroblastoma in the long bones is characterized by a well-defined osteolytic lesion that involves an epiphysis or secondary ossification center, often with foci of mottled calcification(7,16). Intracranial chondroblastoma involving the skull
bones has been reported to have a fuzzily rarefied appearance and sharp demarcation from the adjacent bone by a thin margin of increased density (9,10,17). CT scan confirms the lytic nature of the lesion and shows areas of calcifications in the center and the periphery of the tumor. MRI demonstrates variable patterns. The tumor can show hypointensity on T1-weighted images, hyperintensity on T2-weighted images, and marked contrast enhancement (1), or it can show heterogenous solid and multilobulated cystic components with low signal intensity of the solid component on both T1- & T2-weighted images and fluid-fluid levels of the cystic component with marked enhancement in the solid component and the septa of the cystic part (7).

Our report is the first report of an intracranial extra-osseous chondroblastoma. The imaging findings on CT, MRI and conventional angiography were very similar to meningioma. The preoperative diagnosis of meningioma in our patient was based on the extraaxial and extraosseous location of the tumor and its relation to the dura as well as the signal intensity and pattern of enhancement on MR. The angiogram findings of strong tumor blush with vascular pedicle supplying the tumor in a radial pattern and delayed washout further supported the diagnosis of meningioma, however, the histopathologic examination eventually confirmed the diagnosis of chondroblastoma.
